Recurring Phlebitis of Obscure Origin.—Dr. Briggs, of Washington, D. C., read a paper on Spontaneous Phlebitis. A review of the literature and a consideration of his own cases, led him to the conclusion that there exists a definite group of phlebitis cases characterized by the absence of any inflammatory cause, by a progressive and relapsing course, by frequent occurrence in the veins of the extremities, the clinical similarity to gouty phlebitis but by the absence of symptoms of the lithemic diathesis. The case reported first was said to be characteristic of the group, and the symptoms were given in detail. The patient was a man, aged twenty-two years, and in splendid health. The family history was negative for gout. The patient had had typhoid and pneumonia, but had never done any particularly hard work. In May, 1901, he suddenly awoke with stiffness of the left ankle, followed, in a day or so, by tenderness over the internal malleolus. The internal saphenous vein could then be felt as a cord, and redness and edema, with some lameness, appeared. The acute symptoms subsided in two weeks, a palpable cord being left at the site of the original trouble. In July there was a second attack quite similar to the first, except that it involved the vein higher up. The onset was sudden and without cause, there were redness, tenderness, swelling and pain, and at the end of two weeks the acute symptoms completely subsided, leaving a palpable cord behind. General health remained good, and there was no leucocytosis. In September, October and December similar attacks occurred, the involvement being gradually higher until Poupart's ligament was reached. The onset was always at night, and there was never any warning. Disability was great, edema never marked, and the hemoglobin constantly high. No treatment was used, except cold applications, and the possibilities of embolism were completely disregarded. At present there is a palpable cord reaching to the middle of

the thigh. No edema is present, but there is occasionally a sense of fatigue. About 350 cases of spontaneous thrombosis are reported in the literature, but all of these are probably due to fevers, anemia or cachexia. Tuckwell and Paget, indeed, make the statement that every so-called spontaneous phlebitis is really gouty, a venous thrombosis being, for these authors, as pathognomonic as a tophus and phlebitis being considered not infrequently the sole manifestation of uricacidemia. Dr. Briggs, however, thought that his own case and at least five others in the literature must be considered as a separate group, the absence of any signs of gouty diathesis, the relapsing and progressive course, the obscure etiology and the absence of fever, anemia and cachexia as the cause being the symptom-complex common to all of them. No study of the pathology has ever been made, and any explanation must therefore be based on purely theoretical grounds. It is possible that the first change is in the formation of a sclerosis in the venous wall, and that the patients exhibit an anatomical, rather than a clinical, diathesis. The mortality is probably not high. Rational treatment would seem to be ligation of the saphenous vein above the process in order to prevent the formation of embolus. By the progressive nature of the disease the vein is doomed so that ligation would only accomplish what the malady itself would lead to later.

Coronary Embolism.—Dr. MacCallum showed several pathological specimens. The first was the heart of a man who had died suddenly after a very long illness with endocarditis. The absence of sweats and a relatively low temperature being the features of the case. The right auricle was found free at autopsy, but there were several vegetations on the tricuspid valve. The left auricle was covered with mural vegetations, the chordæ tendineæ were broken, and there were vegetations at the points of closure of the aortic valve. In the left coronary artery there was a corn-like plug similar to the vegetations in the heart. It lay loose in the vessel, there was no propagation of the clot and the vessel wall was intact. These features, together with the sudden death of the patient, seemed to indicate that an embolism had occurred. This condition is indeed rare, and Marie denies it entirely. Welch, however, holds such a position too radical. The cause of the sudden stoppage of the heart after occlusions of the coronaries is not entirely understood.

Polypi in the Intestine.—The intestines were shown of a man who had died after a long illness with dysentery. An abscess had formed in the left iliac fossa connecting with the bowel, and a vesicorectal fistula had later occurred. Cystoscopic examination had shown what was apparently carcinoma of the bladder. This proved at autopsy to be diffuse papilloma, and throughout the intestine were found little tags of polypoid growth which looked like the remaining bridges left by destruction of the intervening mucosa. The appearance suggested that such may be the origin of certain intestinal polyps. Dr. Cole said that he had seen several patients who gave a history of long dysentery, and who showed on proctoscopic examination, many polypi in the bowel. They had been diagnosed "polypoid colitis," but it was thought possible, in the light of Dr. MacCallum's case, that the papillomata might have been secondary and not causative.

Malignant Endocarditis.—Dr. Thayer showed the heart from a patient who had died with malignant endocarditis. He had had a mitral insufficiency for many years, but had kept busily at work with a systolic murmur audible with the ear a slight distance from the chest. Compensation was then fair, and there were no signs of aortic disease. In April, 1904, the patient was much overworked, and began to show a slight steady fever without other symptoms. Fresh endocarditis was suspected. A soft aortic systolic murmur soon appeared, and the heart began to enlarge; and the patient subsequently died, as the specimen showed, with acute aortic disease. Whenever an old heart case begins to show a slight steady fever the prognosis is bad.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held October 13, 1904.

The President, Roland G. Curtin, M.D., in the Chair.

Case of Subphrenic Abscess; With Illustrative Skiagraphs.—Dr. George E. Pfahler in the report of this case referred to the difficulty in diagnosis of subphrenic abscess, and pointed out the duty of using every known method of investigation. The principal object of the report was to call attention to the aid furnished by careful X-ray examination. The patient gave a vague history of an attack of appendicitis beginning ten days before admission to the hospital. On admission he had some fever (101° F.); pulse, 108; respiration, 32. There was slight tenderness in the right iliac region, with increased dulness in the right lumbar region, and an immovable area of dulness above the liver. He had a leucocytosis of 32,200. A diagnosis of subphrenic abscess was given and a confirmatory X-ray examination was made. This showed the right side of the diaphragm displaced upward. It was immobile, and there was a rise in the outer portion of its curve. The lung was clear above. The patient was operated upon, and one and one-half pints of pus were removed. A careful consideration of these points Dr. Pfahler believed would show the valuable additional information given by the X-ray.

Dr. John B. Shober emphasized the value of the X-ray as a confirmatory method in diagnosis, and as an adjuvant in therapeutic work in combination with other methods of treatment.

Dr. William L. Rodman felt that Dr. Pfahler had placed the profession under obligations to him in bringing to their aid another means of distinct value in the diagnosis of subphrenic abscess. A point of special interest, he thought, was the history of appendicitis, inasmuch as subphrenic abscess is generally supposed to be the result of gastric ulcer. The fact that the line of dulness is irregular in outline, Dr. Rodman felt, enables one to differentiate between subphrenic abscess and empyema, which is apt to be the most confusing condition.

The Therapeutic Use of X-ray.—Dr. S. Mason McCollin referred to the diagnostic aid of the X-ray and to the difference in opinion regarding the results obtained by its use. Cases were cited; one had suffered with epithelioma of the lips, so extensive that several surgeons declined to operate on it. Dr. McCollin had commenced the use of the X-ray on it about the middle of July, with daily treatments for the first two weeks; since then every third day. At present the lips are healed, and there is only one large gland under the jaw, which is not more than half its original size. This patient was exhibited to the

Society. One case of malignant growth of the breast, which had been twice operated upon, with an ulcerated surface of 6 x 8 inches, was relieved of all pain, skin formed over the ulcer and life was prolonged nearly one year. A case of non-malignant warty and painful tumors on the sole of the foot was entirely cured by a few applications of the X-ray. Dr. McCollin has also found the X-ray valuable in the absorption of enlarged tuberculous glands. The glands should be removed by the knife and the X-ray treatment instituted. Especial attention was directed to the advisability of applying the X-ray after all surgical operations for malignant growths.

Value of Radium.—Dr. John L. Shober spoke upon the value of radium as a therapeutic agent and cited a number of instances in which he had employed it with distinct benefit.

Treatment of Malignant Disease.—Dr. Charles Lester Leonard made a plea that the X-ray might have more chance in treatment. He regarded Dr. McCollin's case as a beautiful demonstration of the possibilities of this treatment. The present difficulty is, he said, that the X-ray is being asked to cure practically dead patients. What is wanted is the cooperation of the medical men and the surgeons in the use of an agent which has been shown to have such power. The best means known for the treatment of malignancy, Dr. Leonard stated, is early radical operation, and if to early radical treatment there is added the supplementary treatment by the Roentgen ray, there is a combination of the two methods which scientific medicine has shown most effective in treating this scourge of the human race. He particularly emphasized the fact that it is the duty of the physician to have malignant disease operated on as early as possible, if operation is possible, and to supplement that operation by the Roentgen treatment.

Dr. George E. Pfahler spoke of four cases of mediastinal growth at present under his treatment, one referred to him five months ago by Dr. Charles P. Noble, after the removal of a mass in the axilla. To-day the patient, to all appearances, is in perfect health. The other three cases were of too recent record to speak of the result. Two cases of inoperable carcinoma of the uterus have apparently recovered. Improvement had also been noted in another case of carcinoma of the uterus with involvement of the rectum.

Dr. John B. Roberts asked the opinion of the X-ray men of the difference between the action of the X-ray and radium upon sarcoma and carcinoma, whether it be scirrhus or epithelioma, and whether they had arrived at any distinct "dosage."

Dr. W. S. Newcomet said he believed that the X-ray more readily affected the chronic, if such term might be used, form of malignant growths. The question, he thought, was not so much one of dosage, but of a selection of cases.

Dr. Leonard, in answer to Dr. Roberts, said that a dosage in X-ray is practically the same as the dosage in any drug or other remedy; it depends upon the individual and the case. The treatment for epithelioma, for carcinoma and for sarcoma is widely different. The difference in tube, position of patient, etc., are taken into account. The treatment of sarcoma has been shown to be more effective when it has been divorced completely from operation. In a case of a mass of the tonsil filling the pharynx the growth had disappeared under treatment by the X-ray and the patient had been at work for over a year. The patient had been referred to him as inoperable by Dr. John B. Deaver. Differentiation, he said, is made between various growths. Hard growths are more amenable to X-ray treatment than soft; and the less rapid growths than the rapid growths.

Dr. S. Mason McCollin said he thought the difficulty was that physicians did not realize that the object is to get the effect, and this is to be gotten only by experience. In many cases the X-ray must be used almost to the burning point, when the effect is very rapid. When there was a resultant dermatitis an encouraging effect is secured.

The Value of the Stereoscopic Skiagraphy.—Dr. M. K. Kassabian reviewed the history of stereoscopy and described the methods, principles and technic and the application to the art of skiagraphy. He showed a special table and an adjustable plate changer or holder which he devised and by which he had overcome many difficulties. He exhibited X-ray negatives and prints by means of Wheatstone's reflecting stereoscope; also reduced prints and transparencies made from large negatives, by means of ordinary (refracting) Brewster's hand stereoscope. The value of this method, Dr. Kassabian pointed out to be as follows: In anatomy, in studying the structure of the osseous system, trabeculæ, sinuses, grooves, projections, the exact relations of the articulating surfaces of the joints; blood vessels, bronchi and other secretory and excretory canals; in surgery, in cases of fractures, the amount of deformity, the separation being as plainly visible as if the real skeleton were being observed. In dislocations the method will show the exact existing condition, as an ordinary skiagram cannot differentiate the backward dislocation from the forward one because the shadows will be the same. In examination for foreign bodies the surgeon will see foreign body by this method imbedded in the tissue in the relation to other organs. He urged that the method be employed in hospitals and in colleges in teaching anatomy and in private practice.

MEDICAL AND CHIRURGICAL SOCIETY OF MARYLAND.

Stated Meeting, held October 21, 1904.

The Final Results in the Treatment of Congenital Hips: Two Cases Treated by Lorenz.—Dr. Baer reported seven cases showing the results of operative and non-operative treatment in congenital dislocation of the hip. The first patient, a girl of five, had shown a dorsal dislocation of the left hip with a shortening in Bryant's line of 3 cm. Continuous traction was applied for five weeks, and then by means of forcible extension (Bradford's method) the head was brought to the acetabulum and replaced by the Lorenz method. Six months after operation the position was good and the stiffness then present yielded later to massage. Preliminary extension and the use of the extension apparatus at operation proved useful in this case. The functional result had been perfect. The second patient, a girl of five and one-half years, with shortening, external rotation and atrophy, had been operated on by Lorenz at the Johns Hopkins Hospital. The leg was flexed to 90 degrees and abducted, the abductor fibers being ruptured. The posterior muscles and the tissues in front of the joint were then stretched, and a plaster dressing applied; the leg being flexed on

the thigh, and the thigh on the abdomen and the leg flexed posterior to the plane of the body. The acetabulum was poor, and Dr. Lorenz gave a bad prognosis. Marked extravasation of blood occurred in the leg, and persisted for four months. The original dressing was removed in nine and one-half months, and the leg redressed. The anatomical result had been perfect (Bryant's line the same length on the two sides) and the functional result was proven, by the exhibition of the patient, to be equally satisfactory. The other patient treated by Dr. Lorenz on the same day had not done so well. The girl was eight and one-half years old, and the case a difficult one. On removal of the plaster nine months after operation the head was found bulging in the groin, 3½ cm. below and medial to the anterior superior spine, showing that an anterior transposition had taken place. The patient was unable to stand. Operation was done, and a rent in the capsule found through which the head of the femur had slipped. The head was replaced and the functional result was finally good. There was, however, about 2 cm. shortening, possible to correct by a bloody operation. In the fourth case reported the head had been brought to the acetabulum by preliminary extension and reduction then accomplished under ether by the Lorenz method. Six months later the head had slipped out, and this again occurred after a second reduction. At operation a rudimentary acetabulum was found and excavated, the head being replaced and the leg put up in *internal* rotation to overcome anterior bending of the neck. The fifth case showed a brilliant result. The patient was a girl of eighteen years, who had suffered with great pain and disability from double congenital dislocation. She was markedly sway-backed, and walked with a monstrous waddle. Both hips were treated by the open method. New acetabula being formed and preliminary traction being used. The patient had had a very good functional result, in spite of the marked coxa vara of both legs. Lordosis, pain and disability had entirely disappeared. One patient was shown whose convalescence after an open operation had been complicated by the formation of adhesions resulting in false ankylosis of the hip-joint. These had, however, been broken up under ether, and the final functional result was good, though a shortening of one-third inch had persisted. A seventh case showed a fair but not perfect functional result after the bloodless Lorenz method. In this patient anterior transposition of the head had occurred, due to anterior bending of the neck and failure to put the leg up in *internal* rotation. The lessons taught by this series of cases were that operative procedure is the method of choice when anterior bending of the neck is present, that preliminary traction is always advisable, that good results may be expected even in older cases, that the bloodless method is the better method in cases under six years of age (except when an anterior twist of the neck has occurred), and that the bloody method is the operation of choice after the sixth year.

Case of Subdiaphragmatic Abscess; Operation; Recovery.—Dr. Trimble showed a patient who had come to him with a history of a sudden attack of great abdominal pain ten days previous. The man was very ill when seen, pulse was 130, temperature high, abdomen distended. Constipation had been marked, but there had been no vomiting. The lower border of the liver reached below the umbilicus, and the heart and lungs were pressed up and out. A diagnosis of abscess was made. Posterior incision under light anesthesia showed an abscess containing pus and air under the diaphragm. Colon bacilli were isolated from the pus. The abscess was thoroughly evacuated, and a tube inserted for drainage. Temperature soon fell, and the liver receded, but signs of pleurisy appearing an aspiration was done, and no fluid obtained. A rib was then resected, and serum and pus found in the pleural cavity. Both wounds healed without event, and the patient was now well, except for retraction of the chest and a thickened pleura. Dr. Trimble also referred to another case of subdiaphragmatic abscess, and Dr. Watson reports two similar cases, in one of which a perinephritic abscess just under the diaphragm had shown, as the first symptoms, pain in the hip and a slight limp.

Tuberculous Cystitis—The Question of its Primary Nature.—Dr. Wholey reviewed the subject of tuberculous cystitis in connection with a case of his own, in which the condition was possibly primary in the bladder. This disease, according to Metz and Halle, never originates in the bladder for the reasons that concomitant lesions elsewhere are constant, vesical lesions are always less advanced, and hence of an obviously later origin than those found in other portions of the genito-urinary tract, and the vesical lesions are usually found near the vesical orifices (urethral or ureteral). The disease varies in its course from a slow, almost benign condition to an acute and very serious one. Sometimes it occasions no symptoms, and is not infrequently first discovered at the examination for life insurance. Spontaneous recovery has been reported by Paget. The treatment is difficult. Some cases are obviously medical, and others surgical; in the intermediate group of cases it is not easy to say what should be done. At a recent French congress in a discussion of the subject it was concluded that local medical treatment is rarely successful, that curettement, etc., are ineffective, that bladder tuberculosis is always secondary, and that nephrectomy is the only treatment for tuberculosis anywhere in the genito-urinary tract. The failure of surgical treatment is due in part to inability to detect the lesion early. When the disease is limited curettage, excision or cauterization may be of use. Dr. Wholey's patient was a man of eighteen years, with slight tuberculous family history, in whose urine albumin had been found one month previous by an insurance examiner. Frequency of micturition then developed without pain. The lungs were free, the kidneys impalpable. The urine contained a small amount of blood and pus, and many tubercle bacilli. Under irrigations of boracic and carbolic acids and injections of strong bichloride solution frequency had become much less marked, the urine clearer and the bladder capacity greater. There was no involvement of the prostate or epididymis, and the case might be one of primary tuberculous cystitis, though no cystoscopy had been permitted by the patient.

St. John's Guild.—A review of the year's work of this estimable charity shows that 2,500 infants and children have been treated at the New Dorp Hospital and that at least 28,000 babies, children and mothers had open-air outings in the floating hospital ship, the Helen C. Julliard.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held October 10, 1904.

The President, T. E. Satterthwaite, M.D., in the Chair.

Mosquitoes and Malaria.—The evening devoted to the general subject of tropical diseases. The first paper, with the above title, was by Major Junius L. Powell, Surgeon U. S. Army. In it he gave the results of a series of investigations during the past summer at Fort Hamilton, N. Y., as embodied in a report which he had recently made to the Government. There had been quite a large number of cases of acute malarial fever among the troops stationed there, but, although mosquitoes were abundant, the most careful and continued search resulted in the discovery of but a single specimen of the *Anopheles* genus. At the same time, there were conditions about the post and in its vicinity which had formerly been regarded as sources of malaria, and he could not believe, from this experience, that there were means other than the *Anopheles* mosquito by which the infection was conveyed.

Tropical Malaria.—The second paper was read by Dr. John V. Shoemaker, Professor of Materia Medica, Pharmacology, Therapeutics and Clinical Medicine in the Medico-Chirurgical College of Philadelphia. During and immediately after the Spanish-American war he had an opportunity of observing this disease as it presented itself among the soldiers brought to the Medico-Chirurgical Hospital. Having referred to the intensity of the clinical phenomena and to the profound modification which in hot countries occurs in the *Plasmodium* itself, he said that with the recognition of the parasite and the knowledge of its transmission by mosquitoes, the conceptions of malarial infection in its different forms have been rendered much more exact. The profession also gained an immensely important advantage in the posession of absolute scientific tests for diagnosis. The study of the *Plasmodium* in its various phases has enabled us to devise the classification based upon purely clinical phenomena. The malarial paroxysm coincides with the sporulation of a group of the parasites contained in the red blood corpuscles. If the *Plasmodium* is present in various stages of development, the discharge of the spores and toxins is irregular. Accordingly, the typical periodicity of symptoms is disturbed, and the fever assumes a remittent or continuous type. Dr. Shoemaker's worst cases were distinguished by the severity of the symptoms and the irregular course of the fever and were accompanied and followed by extreme prostration. Sometimes, but not always, the fever was followed by profuse sweats. One interesting case displayed a chill every morning and every afternoon for two weeks, each chill being succeeded by fever and sweats. One patient went to sleep at night with a violent headache and woke to find himself in a cold sweat, which was followed by a chill and fever, a reversal of the ordinary succession. In many instances there was such a blending of succeeding paroxysms with the febrile rise and fall that the record approached that of a continued fever. Several of the cases were accompanied by severe bronchitis. In a considerable proportion gastro-intestinal symptoms were marked; nausea and vomiting were common, and some of the men complained of much abdominal pain. Diarrhea or dysentery was met with in some instances; diarrhea in the beginning, followed by constipation, was observed in many. In most of the cases the spleen was enlarged; in some there was splenic tenderness without much enlargement. In several cases there was a marked discoloration of the skin, testifying to the alteration of the hemoglobin by the malarial parasite and its liberation from the red cells. In two cases which bore a close resemblance to yellow fever the men lay in a state of stupor attended with low delirium. The urine was often scanty and high-colored, containing bile-pigment. In several instances there was albuminuria, and in one, hematuria. Many of the cases showed a recurrence after a defervescence of ten days or two weeks.

Diagnosis.—As there were being brought into the hospital at the same time about five times as many typhoid as malarial patients, it was necessary to be extremely careful in the matter of diagnosis. Fortunately for accuracy, we are no longer dependent solely upon clinical observation. The presence, on the one hand, of the *Bacillus typhosus* and the evidence of Widal's test, and, on the other, the detection of the malarial parasite, suffice to settle the diagnosis respectively for typhoid fever or malaria. The cases with marked discoloration of the skin were distinguished from yellow fever by the longer continuance of high temperature and, above all, by the presence of the *Plasmodium malariæ* in the blood.

Treatment.—In the treatment quinine was the main reliance. In the worst cases, where the vomiting was so incessant that the drug could not be retained by the stomach, it was given by the rectum in suppository. The endeavor was made to anticipate the paroxysm by introducing into the system as large an amount of quinine as possible, and as a rule five or ten grains was given every two or three hours. In cases with constipation small, repeated doses of calomel produced movement of the bowels and at the same time served to allay gastric irritability. When diarrhea was present, equal quantities of quinine and salol (usually five grains of each) were combined with good effect. In some instances one-quarter to one-half grain of ipecac was incorporated in the suppository. When nervous symptoms were prominent, cannabis indica or monobromated camphor was combined with the quinine. If the bowel was irritable the suppository was preceded by an enema of starch water and laudanum. When the fever was high, the patient was sponged. None of the cases resulted fatally.

Chief Points of Interest.—The chief points of interest in this series of cases, Dr. Shoemaker said in conclusion, were the gravity of the symptoms, the very marked and prolonged debility, the resemblance of some to yellow fever, and of others to typhoid, the diagnostic value of the scientific test, and the efficacy of quinine administered in suppository when the stomach is intolerant.

Is Mortality Necessarily Higher in Tropical Than in Temperate Climates?—This question was discussed by Colonel Valery Havard, Assistant Surgeon General, U. S. Army, and his contention was that it is not. While it is a fact that mortality has been in the past and still is much higher in tropical climates, he believed that this was not because of the inherent effect of physical conditions, and therefore inevitable, but rather the result for the most part of violations of the laws of health, and therefore preventable. The health of cities is the resultant of many factors, of which latitude is only one and, in Dr. Havard's opinion, not the determining one.

Mortality up to the Present Time Higher in Tropics.—It is as yet impossible to state what should be the minimum mortality attainable by modern sanitary science. Taking, as a basis, the death-rate of the City of New York, 18.18 per 1,000 in 1903, we find that in Manila since the American occupation (four years) the rate has been 45.18. That of last year was 40.85, showing an improvement. The rate for Havana during the decade preceding the Spanish-American War was 36. In the City of Mexico it is commonly about 40, while in India it often rises above 100. During the year 1902 our army was almost equally divided between the United States and the Far East. While at home the mortality from disease was only 5.66 per 1,000, in the Philippines (Filipino troops not included) it was 20.85, or nearly four times as large, and for Filipino troops, 22.59. In 1903 medical officers in the Philippines had learned how to contend against the diseases which beset them, and the mortality fell to 11.14 for American and 18.17 for Filipino troops. It is in wartime that disease mortality runs beyond all bounds in the tropics, owing to the rapid dissemination of epidemic infection among large bodies of men. The highest rates from disease in tropical warfare during the second half of the nineteenth century were noted among French troops in the Soudan in 1888-89, when out of each 1,000 men, 280 died, and in Madagascar in 1895, when, to quote one of their surgeons, "everybody was sick and 50 per cent. died." It must therefore be recognized and admitted that up to the present day there has been a greater liability to sickness and death in the tropics.

The Physical Characterics of Hot Climates Capable of Affecting Health.—The physical or meteorological elements in a hot climate capable of affecting health are chiefly two: (1) Great and continued heat; (2) a high degree of humidity. In the tropics the amount of sweat is enormously increased, the results of which are a diminution of the total amount of blood and a decreased arterial tension. The urine is also much reduced, as well as the output of urea. In consequence of excretory function of the kidneys being diminished, more work is thrown upon the liver. Skin and liver are thus liable to be more or less congested, while the lungs are depleted. As, furthermore, tropical air, through heat expansion, contains less oxygen than that of colder latitudes, the result is decreased metabolism. It is an obvious fact, however, that less oxygen is needed in the tropics, since the calorific process is much less active. High humidity prevents free evaporation of perspiration, and must more or less interfere with the process concerned in heat generation and the active destruction and renovating of tissues, upon which depends bodily and mental vigor. Owing, however, to the constant air movements on tropical islands, this decreased evaporation is less than is generally supposed; so that, for instance, the average summer of Havana is less oppressive than that of Washington and all our Southern cities. The great central physiological condition of human health in the tropics is that the production of bodily heat shall be kept down within certain limits. Nature helps by diminishing the proportion of oxygen in the atmosphere, and we should assist by reducing the food, especially the calorifacient articles of diet. We may further assist by avoiding violent exercise and very active mental work. The result of this necessary tropical régime is a reduction not only of heat but also of nervous energy. By the use of a little prudence and discretion the body may be maintained in a state of normal equilibrium; but the loss of energy is chiefly felt by the mental faculties. Thus, the North American or European going to the tropics will generally find it easier to avoid deterioration of body than sluggishness of mind.

Bacterial Life in the Tropics.—Another important effect of heat and moisture is a great increase and multiplication of saprophytes, so that the decomposition of all organic matter is more rapid and complete. While the part played by saprophytes in reference to human health is rather ill-defined, it is not unlikely that they are more beneficial than hurtful. They are doubtless responsible for unpleasant odors, but it remains to be shown to what extent, if any, decaying animal or vegetable matter, however objectionable to our olfactories and our esthetic sense, is a cause of disease. Pathogenic bacteria are abundantly generated in the tropics, but so they are in temperate climates. The cholera spirillum and *Bacillus pestis* develop as readily on the banks of the Thames and the Seine as those of the Ganges, when given a fair chance. Even leprosy was in past centuries as common in Europe as it now is in Asia. The micro-organisms of typhoid fever and pneumonia are much more at home in temperate or even cold climates than in the tropics. The amoeba of dysentery, however, seems to require a constant high temperature. As to the mosquito, that bloody enemy of the human race, we find it everywhere, increasing in number and blood-thirstiness as we go northward, and rendering life unbearable during the short summer in Alaska and within the arctic circle. There is probably not a single State in the Union where the *Anopheles* cannot be found. Even the mosquito responsible for filariasis is not uncommon in our country. It would seem that the *Stegomyia* of yellow fever does not extend very far north, but probably far enough to make possible an epidemic in any of the large cities of the United Staes.

Most of the Diseases Causing High Mortality Preventable.—Dr. Hayard then took up in succession the principal diseases which are responsible for the high mortality in the tropics, and endeavored to show to what extent they are preventable by the application of the modern laws of hygiene. The report of the Board of Health of Manila for the year ending in April, 1904, he said, would afford a convenient text. In spite of the best efforts of the skilled sanitarians composing the Board, the death-rate still remains about 40, and evidently conditions exist there over which the authorities have but little control. There is a very high mortality among infants, the chief cause of death being assigned as "convulsions," and with a view to reduce this the Board has had prepared for dissemination among the people a circular, giving simple rules for the care of the new-born and the feeding of infants. It is expected that the education of the masses and their relief from utter poverty will in time materially diminish this unnecessary sacrifice of infantile life. In Havana, where the great bulk of the population is white, and of a higher grade of intelligence than in Manila, the infant mortality is lower than in New York. The disease causing the largest number of deaths both in Manila and Havana is tuberculosis; yet, as indicating that the climate is less at fault than sanitary conditions, we find among the Americans and Europeans living in Manila, about 9,000 in number, only 9 cases during the year, or just one per

1,000. Among our troops in the Philippines in 1902 the rate was 1.27, while it was only 0.50 among soldiers at home; but in 1903 the figures were reversed, 0.26 in the Philippines and 0.86 in the United States, the greater ratio at home being partly accounted for by the repatriation of invalided tuberculous patients. The air cure for tuberculosis is easiest, most practicable, and should be most successful in the tropics, but unfortunately there exists in Cuba and all other old Spanish colonies a deeply rooted prejudice against night air, which is believed to be deadly. This prejudice arose, naturally enough, from the havoc caused by those nocturnal pests, the yellow fever and malarial mosquitoes. When Cubans have learned to screen themselves from the mosquitoes without excluding the air, when they realize the value of free aeration night and day, making use of the flat house-roof as a dormitory, and when they recognize the danger of crowding in tenement-houses, as well as the necessity of clothing their naked children, the chances of reducing the death-rate from tuberculosis to the minimum will probably be better for Havana than for New York. One would naturally suppose that where phthisis is so prevalent, other chest affections would be common, but such is not the case; showing, once more, the specific distinctness of pulmonary tuberculosis. Next to tuberculosis, cholera was until recently responsible for the greatest number of deaths in Manila, but this, like other water-borne diseases, is easily preventable, and the Board of Health has succeeded in extirpating it; so that the reports for March and April of this year do not show a single case.

Dysentery is one of the most dreaded of the endemic diseases of the Philippines, not only because of its mortality of 1.18, but also on account of its tendency to become chronic and inveterate. This disease cannot be so easily checked as cholera, but an uncontaminated water-supply would undoubtedly soon put an end to it. In Cuba dysentery is hardly known, only three or four deaths from it occurring during the year in Havana. Beriberi is a common disease in certain parts of the tropics, in Manila causing almost as many deaths as dysentery. For the most part it attacks natives of poor constitution and undermined vitality, and as it apparently results from unsanitary food and surroundings it would appear to be amenable to the laws of hygiene. Yellow fever was once the scourge of the West Indies and South America. American intelligence and energy, during our occupation of Cuba, showed how easily that dreaded infection can be checked, controlled, and then completely extirpated. Malarial fever, in all its protean forms, is common in all warm countries, producing a mortality of 0.93 per 1,000 in Manila, although not a single death among Americans and Europeans. Considering the great mortality of malarial fever in the tropics, especially as seen in various military expeditions, it would seem that the plasmodium parasite possesses there a degree of virulence unusual in northern countries. The positive results obtained by the use of mosquito bars, as well as door and window screens, in this country, Cuba, Italy, the Philippines and other places demonstrate that the prevention of malarial fever, whether mild or pernicious, is a comparatively simple problem. Certain facts appear to indicate that we have in the tropics one or more non-malarial and still unrecognized types of fever. Bubonic plague produced a mortality of 0.49 in Manila, but only one death from it occurred among Americans and Europeans. Typhoid fever was formerly considered a disease of white races and of temperate or cold climates, but later experience has shown that tropical and semi-tropical countries are also liable to become infected. Its victims, however, are mostly foreigners, natives enjoying a large amount of immunity from it. The prevention of smallpox is simply a matter of vaccination in the tropics, as elsewhere.

Both in the Philippines and Cuba diseases of the nervous and circulatory systems constitute a considerable cause of mortality. While in Cuba Dr. Havard was struck with the number of people suffering from arteriosclerosis, a fact for which he was unable to offer any explanation; but as there were only 18 admissions for diseases of the heart and blood vessels, and not a single death among our 3,274 soldiers in Cuba and Porto Rico during the year 1902, the climate could hardly be considered an important factor. Hepatitis and hepatic abscess are generally the result of dysentery, and disappear with that disease. Leprosy is still too common among the natives of tropical and semi-tropical countries. That it could readily be reduced by strict isolation, and in time completely eliminated, there can be no doubt. As its parasite is also common in Europe and in our Southern States, anchylostomiasis, or hookworm disease, can scarcely be considered a tropical affection. The "sleeping sickness" of Africa is produced by inoculation with its parasite through the bite of a fly, and is therefore amenable to the same means of prevention as malarial fever. Bright's disease and acute nephritis, as well as cancer, are more prevalent in New York than in warm countries, and of diphtheria, scarlet fever and measles it may be said that they are a negligible quantity in the tropics.

Climate Plays But a Secondary Role in the Health of Any Country.—From what has now been said it would appear that the high death-rate of the tropics (aside from the great infant mortality characteristic of all semi-civilized populous countries) is due to endemo-epidemic diseases whose cause and mode of propagation are now pretty well understood, and which, therefore, are to a large extent preventable. As a final conclusion, is it not warrantable to say that the climate plays but a secondary rôle in the health of any country, that mortality is chiefly dependent upon the character, intelligence and knowledge of its inhabitants, of their understanding of the laws of hygiene and the extent to which they apply to their own special conditions? In other words, human health in any country is not according to its climate, but according to its degree of civilization and the quality of its government. For the ten years previous to 1898 the death-rate in Havana, as has been stated, was 36 per 1,000. When the Americans occupied it ordinary hygienic measures were at once applied and enforced, and means devised to provide work and food for the poorer classes. The result was that, notwithstanding the absence of any sewerage system, the mortality fell to 24 in 1900 and to 21.20 in 1902; remaining about the same in 1903, under the Cuban Republic. The writer was inclined to believe that when Havana has carried out its intention of constructing a complete modern sewerage system its rate of mortality will speedily fall below that of New York, and that if the Cuban Republic continues to govern itself with prudence and justice, Havana will become the favorite winter resort of North Americans. The fact that during the year

1902 the death-rate among the United States troops in Cuba and Porto Rico was only 3.36, while among those at home it was 5.66, shows that in those tropical islands as soon as American sanitarians had had time to get the prevalent diseases under control and guard the men from unsanitary influences, the ratio of mortality fell below that of the United States. While the death-rate of Manila is still very high (about 40), during the past year the rate among the American element of the population, which is principally composed of adult males, was only 9.05, and among the Spanish, consisting of the usual admixture of men, women and children, 15.45.

Proper Diet for the Tropics.—The last paper of the evening on this subject, was contributed by Dr. Harvey W. Wiley, of Washington, D. C., Chief of the Bureau of Chemistry, U. S. Department of Agriculture. Experience has shown, he said, that with a change of environment the character of the food must also be changed. If it were true that the activities of the human family were the same in all climates, then the quality of food necessary to furnish energy would be practically the same from the equator to the poles. In point of fact, however, human activity is greater in the temperate zones than it is either at the tropics or the poles, and hence the amount of food used up as energy is greatest in temperate zones. The great variant in food is that part of it which is necessary to furnish heat. As the quantity of food for furnishing heat is largest in the polar region and smallest at the equator, tropical foods should be less of a heat-forming character than those used in the temperate zones, and, especially those used in the polar regions. The kind of food par excellence which furnishes heat is represented by the fats and oils, which differ somewhat from the carbohydrates in that the latter are active both in building tissue and in furnishing heat and energy. As the amount of radiation or loss of heat by radiation is less in the tropics than in either of the other zones, the oils and fats should form only a moderate portion of the diet in the tropics. Furthermore, as the degree of activity is usually less by reason of the character of the climate, the quantity of matter necessary to repair waste tissue is evidently less in the tropics, and hence the quantity of nitrogenous food should be less in tropical than in temperate climates.

Fruit Diet Best.—It so happens that nature provides very abundantly in each zone the character of food which is best suited for that region. Thus, in the tropics the indigenous fruits supply most freely the character of food which seems best suited to the nourishment of the people. A fruit diet, as is well known, is one in which nitrogenous and fat elements are reduced practically to a minimum, while sugar and starch are far more abundant. The Bureau of Chemistry has lately taken up a study of many of the tropical fruits, and a table showing the composition of a number of the most common of these was presented. The principal oil food of the tropics is found in the cocoanut and their chief starchy food is derived from the cassava in some of its numerous varieties. The prevailing characteristics of the natural food of the tropics is found in the excessive quantity of sugar which they contain, or, as in the case of cassava, of starch. The amount of protein is very small, and the amount of oil is, with the exception of the cocoanut, not marked. On the whole, it appears that the natural tropical food is one composed of a large excess of carbohydrates, in which sugar predominates. The using of food suitable to the environment is one of the conditions necessary to the preservation of health, and those who go from temperate to tropical climates should be impressed with the importance of gradually changing the character of their diet from the highly nitrogenous one which is characteristic of the temperate zones to the highly carbohydrate diet which is characteristic of the tropics.

BOOK REVIEWS.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. By various writers. Edited by ALBERT H. BUCK, M.D. Vol. VIII. Umb Zym. William Wood & Company, New York.

DR. BUCK is to be congratulated in the completion of this really masterly work. We welcome him to a well deserved rest. The publishers are also to be thanked for the thorough evidence shown that they have desired to give to the profession a thoroughly good book, and both editors and publishers alike that combined the best reference book with which we are acquainted has been prepared.

We have had occasion from time to time to speak in commendation of this project and its performance, It deserves the highest praise. In some regards we cannot see how it might be improved, a few others, however, deserve a more thorough going over.

In matters of inorganic materia medica there have been many lapses—not in the newer drugs—these have been well and consistently handled, but the older friends of the pharmacopœia have not been taken up in the modern sense at all, and the concepts, already obsolete, will further show the effects of time on them.

Of modern pharmacology, save in isolated spots, there is a distinct lack. Here again, older ideas have been set forth, not so much to the present detriment of the work, but to the future student of pharmacology it will prove uninspiring.

Especially commendable have been the articles on histology, anatomy, embryology and pathology. They have been distinctly modern in the truest sense of the word, and have shown a most gratifying breadth of scholarship not often found in a work of this general nature. We wish that the same criticism might be made of many of the articles on clinical medicine and clinical surgery. Most of them have been very excellent, but far too many seem to have been made to order. The pace set by the major part of the book has been too hot for some of the writers, and their contributions do not show up as well as might be expected. It seems to show that our laboratory workers are more keen than our clinicians—an observation which seems not to have escaped our foreign visitors during the past few years.

Taking the work as a completed system, it is one that should find a wide recognition.

THE STUDENT'S HANDBOOK OF SURGICAL OPERATION. By Sir FREDERICK TREVES, Sergeant Surgeon-in-Ordinary to H. M. the King. New edition revised by the author and Jonathan Hutchinson, Jr. W. T. Keener & Co., Chicago.

THIS charming little book, so conveniently put together for pocket use, is abridged from the new edition of the author's "Manual of Operative Surgery." It is intended primarily for students who are preparing for the final examinations, or for those who wish to operate upon the cadaver. In accordance with this intention, all technical detail has been left out which concerns aseptic precautions, and all matters relating to

living tissues. The anatomy of the parts is touched upon only casually and the sole attention given to instruments is a bare statement of the number and kind required.

A great deal of attention is devoted to the chapters on amputations and on the ligation of arteries.

It goes without saying that from the pen of so famous a writer as Sir Frederick Treves, nothing but the best is to be looked for, and endorsements of his style, and his teaching are hardly in place. From the standpoint of the American student, it is most valuable to have presented in so terse a manner the technic of the master of English surgery. It must be stated, however, that the one possible drawback to the use of the book in this country, lies in the fact that many operative measures, which are in general vogue here, are not to be found in the manual, whereas a good deal is presented which is at variance with our American teachings. This, in a measure, emphasizes the value of the fact already noted that the book presents in the terse and direct manner characteristic of Treves, a simple outline of surgical technic as it is to-day practised in England. For comparative purposes, if not for actual reference use, the volume must be of the very highest service to every student. There is no better means to forge fleeting technical facts into the brains, than a comparing of England's technic with our own.

Medical Diagnosis. Special Diagnosis of Internal Medicine. By Dr. Wilhelm v. Leube. Authorized translation from the Sixth German Edition, By Julius L. Salinger, M.D., Physician to the Philadelphia Hospital. D. Appleton & Company, New York and London.

Leube's Diagnosis has been the great book in diagnosis among the German-speaking students of the world. It has been one of the most practical and useful of the works of its class, and Dr. Salinger and the Appletons have performed a really meritorious service in placing it before the American student and practitioner of medicine.

There is little doubt that diagnosis rests at the bottom of rational medicine. Without a correct appreciation of the actual pathological conditions, treatment is largely a matter of hocus pocus, a regular Janus, one side deluding the patient, the other the physician himself. One of the healthiest signs of the condition of medicine in this country has been the great number of text-books on diagnosis; and we welcome this old one in its new guise.

The modest introduction to this American edition by the author bespeaks for it a welcome from its numerous friends, and hopes that it may contribute to the stimulation of the pleasure in the development of medical science and the appreciation of diagnostic art. We feel that it will do this and more, it cannot but help to raise to a higher level of professional efficiency all who study it conscientiously.

Practical Materia Medica for Nurses, with an Appendix. By Emily A. M. Stoney, Graduate of the Training-School for Nurses, Lawrence, Mass.; late Head Nurse Mercy Hospital, Chicago; late Superintendent of Training-School for Nurses, Carney Hospital, South Boston, Mass. Second Edition. W. B. Saunders & Company, Philadelphia, New York, London.

In a subject of such great scope as Materia Medica, it is almost as important to know what need not be taught as to know what to teach, and as a work for medical students must needs contain much of therapeutics and other things of only secondary importance to a nurse, it is a wise plan to have special books for nurses. Of these special books the one before us is to be commended for its suitability to its purpose. The alphabetical arrangement might be criticized, were it not that the author has given a very good therapeutic classification of remedies in the earlier part of the book. The concise and readable type, the inclusion of many unofficial drugs, the added chapters of Poison Emergencies, Mineral Waters, Weights and Measures, Dose and other lists, Abbreviations and Glossary, and, we might add, the employment of thick but very light paper in the making of the book, induce us to give it our highest commendation. A short chapter on prescription-reading might be added with advantage. The doses are given in both English and Metric Systems.

The Theory and Practice of Infant Feeding, with Notes on Development. By Henry Dwight Chapin, A.M., M.D., Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital; Attending Physician to the Post-Graduate, Willard Parker and Riverside Hospitals; Consulting Physician to the Randall's Island Hospital. Second Edition, revised, with numerous illustrations. William Wood & Company, New York.

It is only a short time since we commended the author on the readableness of his first edition. There the principles of infant-feeding and the method of obtaining good milk were discussed at length. But so much work has been done recently in this field that the author has found it advisable to introduce new matter in many places. The supposed distinctive difference of breast milk being alkaline and cow's milk acid has been proven a fallacy. Alkalies added to milk prevent the stomach secretions from curdling the milk and enable it to pass into the intestines in a soft or fluid condition. These are some of the newer findings. Many minor changes have been made throughout the book, and it will doubtless be received with favor by physicians, as was the first edition.

A Compendium of Chemistry. By Dr. Carl Arnold. Translated by Dr. John A. Mandel. John Wiley & Sons, New York.

Arnold's work has always received special support from the student of chemistry, and even the professional man, by reason of its conciseness and philosophic grasp of general chemical principles.

It is particularly opportune to have at this time a translation of so modern a book, and we feel assured that it will serve the useful purpose it has served for so many years in the home of its early appearance.

BOOKS RECEIVED.

Year-Book of the Medical Association of Greater New York. 8vo, 193 pages. Published by the Association.

Action of Light as a Therapeutic Agent. By Dr. L. K. Hirshberg. 8vo, 49 pages. Snow and Farnham, Providence.

How to Cook Food for the Sick and Convalescent. By Helena V. Sachse. 12mo, 297 pages. J. B. Lippincott Co., Philadelphia.

Studies from the Rockefeller Institute for Medical Research. Volume II. 1904. 8vo, 250 pages. Illustrated. Published by the Institute.

Suppression of Tuberculosis. By Prof. E. von Behring. Translated by Dr. Chas. Voldman. 12mo, 83 pages. John Wiley & Sons, New York.

A CASE OF ENTERIC FEVER COMPLICATED BY POLYURIA.[1]

BY J. C. WILSON, M.D.,
OF PHILADELPHIA.

THE moderate polyuria which often attends the period of defervescense and early convalescence in the acute febrile infections is too well known to excite comment, and the literature abounds in instances of glycosuria as a complication of these diseases. But transient non-saccharine polyuria at one time exceeding, as in the following case 6,000 c.c. in twenty-four hours, developing in the course of an attack of enteric fever and subsiding with the decline of the temperature, must be very rare. I have never before had the opportunity of observing such a case, and such examinations of the literature as I have had made fail to discover analogous cases. Very recently, I learn that my friend, Dr. Fussell, has observed a similar case, which he will report on this occasion. For nosological purposes it would be well if the distinction between polyuria as a symptomatic and transient condition and diabetes insipidus as a substantive affection, a distinction corresponding to that between glycosuria and diabetes mellitus, were more generally observed.

Enteric fever with prolonged and peculiar delirium in a male adult, complicated by massive polyuria developing in the mid-course of the attack and subsiding with the fall of the temperature. Treatment, systematic cold bathing. (Notes by Dr. Kalteyer.)

REPORT OF CASE.

J. W. V., aged twenty-nine years, single; birth place, Michigan; occupation physician. Admitted to the medical ward of the Jefferson Hospital September 25, 1902.

Diagnosis.—Enteric fever, complicated with polyuria.

Family History.—Father, mother, two brothers and one sister living and in good health. There is no history of neuropathic, cardiac, or tuberculous disease in the family. The patient's mother suffered from cancer of the breast, which three years ago was successfully removed by operation and has shown no signs of recurrence.

Previous Personal History.—The patient was informed that he had measles and chickenpox in early childhood. At the age of six years he suffered from diphtheria. Some years ago, he had an attack of catarrhal jaundice which lasted for about ten days. At twenty-six years, he suffered from an acute illness of about a week's duration, which was said to be acute appendicitis, the principle symptoms of which were colicky abdominal pains, at first general and later localizing itself in the right lower abdominal quadrant; vomiting and fever. He made an uneventful recovery without operation, and so far has not had a relapse. After this illness he enjoyed good health until the present illness. He has never suffered from Neisser's disease or syphilis; he has used alcohol moderately and smoked occasionally.

History of Present Illness.—Four days prior to his admission into the Jefferson Medical College Hospital, he complained of loss of appetite, malaise, and severe frontal headache. The patient states definitely that previous to September 21 (four days before entrance into the hospital) he appeared to be in excellent health; his duties, which consisted of an obstetrical practice in Philadelphia, made great demands upon his time. During the past summer he was in the habit of drinking unfiltered and unboiled water. On Monday morning, September 22, his condition had somewhat improved; he had slight browache, although soreness in the muscles of his limbs was a prominent symptom and his appetite remained impaired. On Monday evening his temperature registered $99^{2}/_{5}$° F., headache grew worse, and becoming somewhat anxious about his condition, he took 1½ grains of calomel in divided doses. On Tuesday morning he had a loose bowel movement; his temperature registered 99° F., headache was now constant and distressing, and weakness pronounced. In the evening his temperature registered $101^{2}/_{5}$° F. On Wednesday morning, the temperature was 101° F., his condition was decidedly worse, and in the evening the temperature rose to 103° F., during the course of the day the symptoms previously mentioned intensified. He took to his bed on Thursday morning, when he was admitted to the hospital.

Condition on Admission.—Temperature 101.2° F. (axillary); pulse rate, 90; despiratory rate, 20; cheeks flushed; pupils dilated, and the tongue coated lightly on its dorsum with a whitish fur. The abdomen was somewhat tympanitic, the spleen could not be palpated, but on percussion evidence of enlargement was noted. The heart and lungs appeared normal.

Blood examination revealed the following:

Erythrocytes	4,580,000 per cubic millimeter
Leucocytes	8,600 per cubic millimeter
Hemoglobin	80 per cent.
Color index	.88

The blood gave a positive agglutination reaction with the *Bacillus typhosus*.

The urine did not give Ehrlich's diazo reaction.

On September 27, two days after admission,

[1] Read by title at the meeting of the Association of American Physicians, May, 1904.

a single rose spot which disappeared on pressure and reappeared when pressure was released, was discovered in the epigastric region.

The treatment ordered on admission was as follows: Liquid diet—milk, broths, etc., at three hour intervals; one grain of calomel in divided doses. Sponging with water having a temperature of 60° F. when his axillary temperature rose as high as 102° F., and tubbing in water at 70° F., when his temperature registered 103° F. or higher, every three hours. During the plunge a half a dram of aromatic spirits of ammonia was administered. At intervals of six hours a Leiter's coil was applied over the heart through which hot water was passed for about a minute and then cold water for about twenty minutes. On October 1, when Prof. Wilson took charge of the service, the treatment was modified. The diet was unchanged, but other measures were discontinued, and bathing in water having a temperature of 70° F. was ordered every third hour craving water which was given to him in liberal amounts. The delirium became more severe during the third week, when a peculiar wandering of mind was present. He frequently complained of thirst, and became difficult to manage.

His mental agitation was accompanied by considerable restlessness. As a rule, the delirium conformed to an active type and the patient often engaged in conversation with those about him. He was in the habit of discussing various medical topics incoherently, and his thoughts seemed to dwell upon his condition. The mental derangement continued into convalescence and subsided very gradually. Subsidence of the polyuria was also gradual. On October 16, valerianate of zinc in one-grain doses and ergotine in three-grain doses were administered three times per day. After he had fully regained consciousness, he remarked that he recalled but few events of his illness except that his mind was often clear during and for a short time after the plunge.

when the temperature in the axilla registered 101.5° F. The patient was given one-half ounce of whisky during and after the plunge.

The disease seemed to run a typical course except that delirium of a low wandering type later becoming very active, manifested itself early and was quite constant, abating only after the plunges, when, as a rule, the mind remained clear for a short time. Crops of rose spots were observed from time to time.

The lower edge of the spleen was palpable during the second week. The pupils remained dilated; the tongue became very dry, and its coating was thick and brown. He often complained of dryness of the mouth. Constipation prevailed during the entire course of the illness, being especially pronounced in convalescence. Enemata were given at regular intervals. Emaciation set in rapidly. The quantity of urine began to increase on October 5, and urination became frequent. The highest amount voided was 215 ounces on October 16. The patient suffered from an unquenchable thirst. He was constantly

Polyuria was a most conspicuous sign and while this was most marked, micturition was so frequent that is was necessary for the patient constantly to have a urinal either upon his bed or upon the table adjoining it.

The accompanying chart shows the daily variations in the amount of urine during the course of the illness:

Urine examination, September 27, 1902.—The quantity of urine for the twenty-four hours preceding was 30 ounces. Color, amber; transparency, clear; specific gravity, 1.018; reaction, acid; albumin, a faint trace present; sugar, not present; urea, 2.1 per cent.

Microscopical examination.—Amorphous urates, squamous epithelial cells, and a few granular casts were found.

Urine examination, October 8, 1902.—The quantity of urine for the twenty-four hours preceding was 55 ounces. Color, straw-colored; transparency, clear; specific gravity, 1.003; reaction, acid; albumin, a faint trace present; sugar, not present; urea, .7 per cent.

Microscopical examination.—Amorphous urates and squamous epithelial cells were found.

Urine examination, October 11, 1902.—The quantity of urine for the twenty-four hours preceding was 80 ounces. Color, straw-colored; transparency, clear; specific gravity, 1.004; reaction, acid; albumin, a faint trace present; sugar, not present; urea, .8 per cent.

Microscopical examination.—Amorphous urates and squamous epithelial cells were found.

Urine examination.—October 16, 1902.—The quantity of urine for the twenty-four hours preceding was 215 ounces. Color, straw-colored; transparency, clear; specific gravity, 1.005; reaction, acid; albumin, a faint trace present; sugar, not present; urea, .6 per cent.

Microscopical examination.—Amorphous urates and a few squamous epithlial cells were found.

Urine examination, October 18, 1902.—The quantity of urine for the twenty-four hours preceding was 130 ounces. Color, light straw color; transparency, clear; specific gravity, 1.001; reaction, faintly acid; albumin, a faint trace present; sugar, not present; urea, .3 per cent.

Microscopical examination.—Amorphous phosphates and a few pus cells were found.

Urine examination, November 17, 1902.—The quantity of urine for the twenty-four hours preceding was 40 ounces. Color, amber; transparency, clear; specific gravity, 1.015; reaction, acid; albumin, not present; sugar, not present; urea, 1 per cent.

Microscopical examination.—Amorphous urates, in a few epithelial cells, and a few pus cells were found.

The total amount of urea for periods of twenty-four hours, was increased at the height of the polyuria, and the accompanying chart illustrates the variation in the total amount.

Convalescence was uninterrupted and uneventful. The patient was given a soft diet after his temperature had remained normal for seven days.

He was discharged from the hospital on November 25, 1902, and has remained well until the last report about the close of the year 1903.

After the polyuria had reached an amount which excited our special interest, a daily record of the quantity of fluid ingested was kept. It is a matter of regret that this document, which properly forms part of the history of this case, has been mislaid. The polydipsia was as marked as the polyuria, and no restriction was placed upon the amount of water given the patient except that no single draught should exceed two ounces, it having been found that the craving recurred as quickly after larger quantities.

I have no hypothesis to offer as to the significance of the polyuria in this case. It was evidently the cause, not the effect of the great intake of fluid; the patient was neurotic and overworked but did not present the symptoms of any organic disease of the brain or nervous system. It cannot, in view of the enormous number of cases of enteric fever that have now been treated by systematic cold bathing, be ascribed to that measure, since many accurate studies of the urine have shown a very constant moderate increase but no such enormous output as in the foregoing case.

REPORT OF THE MEDICAL DIRECTOR OF ST. JOSEPH'S SANATORIUM TO THE ADVISORY BOARD.

BY E. S. BULLOCK, M.D.,
OF SILVER CITY, NEW MEXICO.

The establishment of St. Joseph's Sanatorium was an attempt, the first, I think, to supply the need of a properly equipped, closed institution, for the treatment of tuberculous invalids in the Southwest. During my own often ill-advised wanderings over the arid region in search of health I was continually reminded of the necessity for such an institution, both by my own observations and from seeing the experiences of others. As time went on it became my ambition to provide such a sanatorium at some especially favored spot in the Southwest, to fill what seemed to me a crying need. An idea also took shape in my mind that the exact formulation of the value of climate in phthisiotherapy is of great importance to medical science. After six years daily work among consumptives out West I still lack the data which would determine the precise value of climate in the treatment of tuberculosis. A small number of cases is a very insecure basis for the derivation of scientific statistics, and for this reason I have not yet been able to see the truth clearly, much less to aid others to do so to any extent. Amid the conflicting opinions as to climate and its value (the positive statement of Dr. Flick that equally good results can be obtained in Philadelphia, and that no less certain opinion of Dr. Solly that climate is of prime usefulness), I decided that to bring order out of confusion would require extensive data from an institution located in the very center of a favored zone and complying with all the requirements of modern phthisiotherapy. I trust I have made clear the ideas which constitute the very foundation of St. Joseph's Sanatorium.

By meeting and knowing the Reverend Mother Paul of the Order of Sisters of Mercy, to whose clear-sighted intelligence St. Joseph's owes its existence, I was enabled to take the first steps in the realization of my ambition. We chose Silver City as the proper location of our prospective institution for the same reasons which actuated the army officials in selecting Fort Bayard as the site of the Government Sanatorium. They had an extensive experience in the Southwest, and were thus well aware of the fact that summer and winter, year in and year out, Grant County, New Mexico, provides the ideal in atmospheric environment. Glorious sunshine, maximum dryness, cloudless skies, warm winters, cool summers, an air so clear that on moonlit nights one can see the trees on the mountains twenty miles

away, these with little dust and comparative freedom from high winds, and all at the most favored altitude, 6,000 feet, make the sum of the climatic advantages of the mountainous portions of Grant County.

During the summer of 1901 I resigned my position as pathologist at Fort Bayard and came to Silver City, to aid in establishing the institution which forms the subject of this report. At Silver City the Sisters had a small building, with five suitable rooms opening upon a porch and available for patients. They had, however, plenty of ground and trees, which, as the institution developed, made a valuable feature. The small building mentioned, which is now used as an infirmary, was the nucleus of our present plant. In order to insure the perpetuation of our ideals it seemed important that the scientific management of the institution should be vested in an Advisory Board composed of men especially interested in tuberculosis. Such a Board was at once instituted, and has proved our most valuable asset; for its members have sent us most of the few patients we have had, and have always been ready to furnish opinions upon matters submitted to them. As at present constituted this Board consists of the following members: Drs. J. Solis-Cohen, Philadelphia; S. Solis-Cohen, Philadelphia; W. C. Glasgow, St. Louis; H. M. King, Liberty, N. Y.; Seymour Oppenheimer, New York; E. Fletcher Ingals, Chicago; E. L. Shurly, Detroit; S. E. Solly, Colorado Springs; J. N. Mackenzie, Baltimore; J. C. Wilson, Philadelphia; H. L. Loomis, New York; J. H. Musser, Philadelphia; J. R. Arneill, Denver; C. G. Jennings, Detroit; J. H. Burtenshaw, New York; J. B. Huber, New York; R. B. Preble, Chicago; Alfred Meyer, New York; A. R. It was the idea of those in immediate control of the institution that as soon as it became practicable the medical part of the work at St. Joseph's should be under the supervision of this Board, that its control in this respect should be actual rather than nominal and honorary. To-day seems a most auspicious occasion for the carrying out of this idea; and I am here as the representative of the Sisters of Mercy to tell you about our work, to try and make you understand what we are doing out in the desert, and thus to realize one of our most cherished ambitions. It is our hope that you will form such an organization and elect such officers as will best serve this valuable scientific project. I am sure that I do not overstate the case when I dwell upon what such an institution in the Southwest means to medical science, and particularly to the unfortunate class sent West in search of health. Following the organization of the Board, the power to elect new members to it will be in the hands of its members.

It has always been our practice to send to the home physician a monthly report of the patient's progress. This, it seems to me, is a wise plan and one that should be continued, for it enables the physician sending the patient to follow the case and witness its termination, and also serves to maintain his interest in the work.

In order to provide suitable accommodations for patients it soon became necessary to erect additional buildings, and six months after the establishment of St. Joseph's, money was borrowed for this purpose and work commenced. The ambulant building, so-called from the fact that it accommodates patients without fever, is built around a court filled with trees. It is but one room thick, and without halls, which in our climate are unnecessary and would make dead air spaces unsuitable for ideal ventilation. It has a porch on both inner and outer sides, in all 600 feet long. Each room opens upon the porch from both sides. A building so constructed, with brick walls between the rooms, really forms a series of cottages, and has proved most convenient as regards the handling of patients and their personal comfort. In our region the atmosphere is rarely perfectly still, even at night, and careful investigation has proved to me that in these rooms the patient gets a constant supply of pure air. On this account we do not make any special feature of sleeping out of doors, though patients are permitted to do so if they so desire.

Each room is connected with the Sisters' dormitory by an electric bell. The rooms are heated by small stoves, though a fire is only required in winter when patients get up and again when they go to bed. The buildings are all lighted by electricity. A large recreation room with billiard table and other amusement features occupies one corner of the ambulant building. In the basement of this building, all above ground, are the executive offices, laboratory, and hot water heating apparatus. An adequate supply of bath and toilet rooms connect with a private sewer. The present debt of the institution was the cost of the ambulant building. Our present capacity is twenty-five patients, though as yet all the rooms have never been occupied at one time. We do not contemplate a much larger plant, for careful individualization of cases, so necessary to the highest success, is not compatible with a large number of patients. A few tent cottages, for the accommodation of patients desiring them, have been erected, though when a building constructed with every attention to ventilation can be obtained, I much prefer it to the less durable tent cottage. Patients without fever take their meals in a common dining room, and on account of the small number of women, a separate dining room is provided for them.

As far as possible and consistent with humanitarian action, hopeless cases are excluded. If

after sufficient observation I am convinced that nothing is to be gained by further treatment, I do not hesitate to advise a patient to go home, for this is not only just to the patient in question, but also to the others, as the depression which always follows a death in an institution where the patients are known to each other should be avoided if possible. From the beginning it has been the object of those in charge to make the cost of treatment as low as possible. On a basis of our present average of 15 patients $100 per month is the lowest rate compatible with meeting our obligations and the ordinary expenses of the institution. When a larger number of patients render it practicable we hope to reduce the cost. The rate of $100 per month includes everything required by the patient except clothing. It will be impossible to contemplate the establishment of a free department, which we have always had in mind, until we possess an endowment, and when the isolation of our location and the poverty of the Southwest are considered, it seems that the acquisition of such a fund must be a good way in the future.

As regards the features of daily life which contribute to cure, the discipline maintained in rigid. We have never hesitated, no matter how badly we needed the patient, to discharge anyone who, after due warning, refused to follow instructions. Patients are not permitted to leave the institution without the consent of the physician in charge. All sputum is placed in individual paper spit-cups, which are collected and burned as often as necessary. The rooms are wet-cleaned daily, and all bedding exposed to sun disinfection every day. Each room is carefully disinfected with formalin upon being vacated. Patients with constant slight fever, or those in whom the daily maximum temperature is over 100° F., are given actual cadaveric rest in the open air. Those with a normal temperature, or those in which the daily maximum temperature is above normal but less than 100° F., are given rest or moderate exercise as seems indicated. There is nothing I have come to fear more than too much exercise. Even in normal temperature cases, I am a firm believer in only sufficient exercise to maintain appetite and digestion.

Unless otherwise indicated, all patients are fed six times daily; three full plain meals and light feedings between meals and at bed-time, usually consisting of eggs, milk, bread, and butter. Each patient is visited every day, and those in the ambulant class report to the office of the Medical Director each morning for observation and treatment. Following the theory that disinfection of the air passages may prevent the infection of new areas, each patient is given every day an inhalation of a nebulized solution of trikresol and methylendiamine. All inflammatory processes of the respiratory organs receive careful attention. Sputum adherent to the larynx is washed away. Tuberculous complications of the accessible respiratory organs are treated twice daily. The principles which underlie all our therapeusis should be termed physiological, for by means of careful, persistent individualization, an attempt is made to maintain each and every organ at its highest efficiency. As I understand it this constitutes almost the whole of phthisiotherapy to-day. Once a month, or oftener if necessary, each patient receives a thorough examination, including sputum, blood, and urine.

Lack of space will not permit more than a passing reference to a few of the most interesting aspects of treatment. There are, however, some matters in this connection to which I desire to refer briefly: As long as progress towards health is uninterrupted it is my practice to treat patients upon strictly physiological lines, though always being ready to interfere if things go wrong; for, instance, a reasonable time is allowed to pass after placing patients under proper conditions, and if the fever still persists, a series of sputum examinations is made to determine if the streptococcus is constantly present. If so, the patient receives streptolytic serum, which under such conditions had been of great assistance to me. Even if it does not cause a complete removal of febrility there is frequently an amelioration of fever as well as of other toxic symptoms. My experience has been that if the streptococcic infection can be removed the patient is much better able to handle the tuberculous and other infections, and often does so. There are times when the use of this serum seems a direct life-saving measure, converting an apparently hopelessly febrile case into an ordinary one. In continuously febrile cases, in which every means employed fails to lower the temperature, nothing remains but to send the patient home, for as I shall be able to indicate statistically later, climate, with everything else, must be admitted to be nearly a complete failure in this class of cases.

In very chronic cases with cavities and extensive fibrosis, in which the sputum is difficult to raise, the fluid extract of coccillana has often proved valuable. I have a number of such cases in which the patients state they could hardly dispense with it. Coccillana is best administered in a syrup in doses of fifteen to thirty drops every three or four hours. In hemorrhage, and especially chronic blood-spitting, we have a potent remedy in the chloride of calcium, which may be employed in much larger doses than are usually recommended. When given well diluted with water I have never seen it disturb digestion. Carbonate of guaiacol, carbonate of creosote, and benzosol, have a well-defined usefulness in the treatment of the associated infections of pulmonary tuberculosis. In pure tuberculosis in which there is a normal temperature I have never been able to convince myself that they are of any value. Their field is found in those febrile cases in which the streptolytic serum is either not indicated or is insufficient to remove all of the mixed infection. Benzosol and the carbonate of

guaiacol may be used for quite extended periods without disturbing digestion, and are, in fact, often beneficial in fermentative indigestion, especially that form associated with foul breath.

One of the hardest tasks presented to the phthisiotherapist is that of preventing undue loss of body proteids, and for this purpose ichthyol is second only to a proper dietary in aiding nutrition and arresting loss of weight. I have frequently tested its use by withdrawing it from a patient who was apparently thriving upon it, and immediately loss of weight would follow, to be checked only when ichthyol was again prescribed. Irrational as it may seem with our present knowledge of tuberculosis I am quite ready to say a good word for counter-irritation in the form of blisters applied over an active lesion. I have seen temperature drop a point or two coincident with their employment, especially if the bleb is carefully preserved and the serum permitted to resorb—a point I learned from my friend Dr. J. Solis Cohen.

In laryngeal tuberculosis, especially of the ulcerative type, I am convinced that frequent disinfection with formalin is a valuable procedure. In such cases, in those who can be taught to do it, I direct the patient to spray the larynx with formalin solution several times daily, and twice every day they report to me for careful mopping with the same solution. After all is said and done I am, however, convinced that in this class much more depends upon getting the patient into good condition than upon any local treatment. When the patient improves generally, improvement in the larynx usually follows, and per contra, in a steadily failing patient nothing but relief of pain is accomplished by laryngeal medication.

Anent the discussion of the place of climate in phthisiotheraphy, it seems worth while to mention some facts deducible from our experience. A case is often sent to us in which the patient before leaving home was having a daily chill, high fever, sweats, and profuse expectoration. Immediately upon his arrival in our climate these conditions are changed. The chills and sweats cease, fever comes down from two to three degrees, and the sputum is greatly diminished in quantity. Such an experience is much too frequent to be accidental, and too sudden to be accounted for by change in management, and if such a manifest amelioration occurs in otherwise hopeless cases, what must be the climatic influence in a more hopeful class? Though not so graphically presented it is probably none the less actual and positive. Among our patients sweats and chills, and diarrhea not due to tuberculosis of the intestine, are so rare that I can with difficulty recollect having prescribed for a patient presenting them. We have a number of patients with very chronic and extensive lesion, who occasionally come to us for advice and treatment. Should such go home for a visit they are always glad to return and again experience the resulting amelioration in symptoms which had developed and become annoying during the stay at sea-level.

An almost complete absence of pleurisy and pleuritic pain is evidently accounted for by the quiet sanatorium life. Hemorrhage is with us a very occasional manifestation of pulmonary tuberculosis. At St. Joseph's six months at a time have elapsed without the occurrence of a single hemorrhage. This is, of course, partly accounted for by the quiet life the patients lead, and yet some credit should undoubtedly be given to the diminution in atmospheric pressure which follows residence at a high altitude, an experience substantiated by experience with the pneumatic cabinet.

The apparent permanency of the different types of pulmonary tuberculosis is a characteristic worthy mention. For instance, cases in which the temperature does not drop below 100° F. within a reasonable time after admission—a month or two—remain permanently febrile. Cases afebrile upon admission, or those in which the temperature drops below the febrile point shortly after admission also exhibit the same marked permanency of type, as do the afebrile cases without bacilli in the sputum. This characteristic is often of great assistance in making a prognosis during acute exacerbations, for in chronic tuberculosis, with few exceptions, the future course of the disease will be like the past. As regards the length of time necessary to effect a cure, even in incipient cases, I have changed my ideas very much. It is, I am sure, much longer than we have been led to suppose. At St. Joseph's it is only seldom that I am privileged to witness a genuine cure. Human nature is such that even in cases in which progress toward health is constant and uninterrupted, patients will not remain under treatment longer than about six months. It is a fact that the more rapidly they improve the more difficult they are to control. Very great improvement is the rule at our institution, but cures require more time than patients will allot to it, even though money may not be a consideration. Lack of means is, of course, an insuperable obstacle to a long stay, though it occurs rather more infrequently than might be expected. As an offset to this tendency to break treatment after about so many months have elapsed, it is our practice to keep in close touch with our discharged patients in good standing, that is, those who leave the institution with our consent, and to maintain our connection with the case as long as the patient remains in the country. It is our desire that until ready to go home they should look to the institution for guidance and help in time of need. Occasionally it is my privilege to witness a truly wonderful struggle for life and health, very gratifying to one who so often sees the discouraging frequency with which patients will break their connection with a system which has proved so profitable to them. It is a fact that those having the hardest struggle make much the more creditable and persevering patients.

With the exception of an occasional cold we

have never witnessed any intercurrent affection among our patients. This is, it strikes me, the highest possible tribute to the hygienic environment, climatic and otherwise. This absence of complicating diseases must be very advantageous to the pulmonary invalid. A most careful study of family histories seems to indicate that a distinct family predisposition to the disease is really a rare phenomenon, if it exists at all, and that favorable opportunity for infection plays the leading rôle in causation. A previous depreciated condition of the body due to acute illness, particularly other infectious diseases, seems to have a direct connection in many cases with infection with tuberculosis.

In regard to the presence of adventitious organisms in the sputum, I am quite sure that their number and the frequency of their occurrence depends very largely upon whether the sputum has been contaminated with mouth and throat organisms. The smaller the quantity of sputum and the more difficult it is to raise, as in incipient cases with few or no bacilli, the more constant is the occurrence of adventitious organisms. It thus follows that it is a great mistake to make a diagnosis of mixed infection from sputum findings alone. The clinical picture of sepsis must be, after all, the real criterion.

A diazo reaction in the urine is confined to hopeless cases as a rule, though occasionally present during acute exacerbations. The constant presence of this reaction is, of course, an indication of great disorganization of metabolism, though not at all necessary to an unfavorable prognosis, the clinical picture being amply sufficient for that purpose in such cases.

As regards the blood findings in tuberculosis, nothing except the presence or absence of anemia is of much importance clinically. Marked degenerative changes, like the diazo reaction, occur, as a rule, only in very unfavorable cases. If fever is present there is always a leucocytosis, which varies constantly with the degree of fever; therefore, to know the leucocytosis it is only necessary to be familiar with the temperature, except, of course, in miliary tuberculosis, in which leucocytosis does not occur. The presence of anemia is much more correctly indicated by the appearance of the patient than by any instrument so far devised. In very chronic cases especially, in which there is an anemia of quantity rather than of quality, so-called instruments of precision fail to indicate the condition. In this type of anemia I have not been able to see that the administration of iron accomplishes anything. If upon admission a patient presents a marked degree of anemia, as shown either clinically or by the hemoglobin scale, it is my practice to administer iron. If the degree of anemia is slight, I pay no attention to it unless it persists, which generally is not the case, the blood condition correcting itself, as a rule, within a short time. With us a count of the red cells is of very little value, for upon coming to a high altitude there is such a rush of immature red cells to the periphery that the erythrocyte count is very misleading. I have often seen a count of 7,000,000 to 10,000,000 red cells in a patient who presented unmistakable clinical signs of anemia. Mixed infection is almost always accompanied by anemia, and in such cases iron should be given from the start.

Under present conditions at St. Joseph's, it seems wrong to send us patients who cannot afford to remain under institutional care at least six months, and, if possible, able to stay a year if it seems necessary, if not all the time in the institution, at least under our direction. Our experience is that six months' institutional treatment usually suffices to place a patient on the safe side, so that with a little help now and then he may be trusted to look after himself, after spending the period mentioned under our immediate direction. In advanced cases especially, the patient should be warned that a great deal of time is necessary to accomplish a good result, and then when month after month passes and still a long period of invalidism is ahead, disappointment will not be so general nor so keen. It is very foolish, I am sure, to put a time limit upon tuberculosis, and when done often leads to such grave disappointment as seriously to handicap the patient in the struggle for health.

In examining the stastistics of any institution in the arid region it is important to keep in mind the fact that a large proportion of the cases belong to an advanced class, those in which the patient has been sent West only as a last resort. To my mind, the small percentage of incipient cases explains the comparatively great length of time treatment must be continued in order to get clinical cures, as well as their comparative rarity in institutional work out West.

One hundred patients have been admitted and discharged from the date of the establishment of St. Joseph's Sanatorium to the present time. Of these, 25 were discharged or died during the first month, and therefore will not be included in our statistics. They were all hopeless cases, and with the exception of those who died were all sent home as soon as possible. For the sake of perfect fairness five cases in which the bacillus could not be demonstrated have also been omitted, even though in all the patients made good recoveries. As we employ it, the term "clinical cure" means a normal general condition and temperature, freedom from signs of activity in the lesion, absence of bacilli in the sputum, and practical absence of cough and expectoration. Deducting the 25 cases under treatment less than a month, and the five in which the diagnosis could not be confirmed, leaves 70 cases to be considered in this report. In 12 or 17 per cent., a laryngeal lesion was present. In five of these or 42 per cent., the laryngeal lesion was cured. In three or 25 per cent., there was improvement, and in four or 33 per cent., we failed to control the laryngeal complication. Even though the number of our laryngeal cases has been very small the results

have been more than good. I have come to feel a certain sense of power in laryngeal tuberculosis, based upon results at Fort Bayard as well as at St. Joseph's Sanatorium, especially when there is absence of ulceration.

For the purpose of elucidating our results I have utilized both the old classification of three stages, and one of my own devising, and based upon the degree of mixed infection present, as indicated by the temperature, though, of course, not without a due sense of the deficiencies in our knowledge of the allied infections of tuberculosis. It, however, requires but little experience with pulmonary tuberculosis to recognize that prognosis depends very largely upon the degree of fever present, or what amounts to the same thing practically, the extent and gravity of the mixed infection. The size of the lesion and its character is of relative insignificance, and I have, therefore, also divided the cases into those with little or no mixed infection, and those with well-marked clinical mixed infection. Regardless of classification the general results are as follows: Three, or four per cent., died; 12, or 17 per cent., were unimproved; 38, or 54 per cent., were improved, and these, one should bear in mind, were nearly all potentially curable cases if treatment could have been continued long enough, and 17, or 24 per cent., were clinically cured.

In 25 cases there was infiltration alone, and of these one, or four per cent died; two, or eight per cent., were unimproved; 12, or 48 per cent., were improved, and 10, or 40 per cent. were clinically cured.

In 21 cases there was consolidation, and of these, one, or five per cent., died; one, or five per cent., were unimproved; 14, or 66 per cent., were improved, and five, or 24 per cent., were clinically cured.

In 24 cases cavities were present, and of these, one, or 4 per cent., died; nine, or 37 per cent., were unimproved; 13, or 54 per cent., were improved, and one, or four per cent was clinically cured.

It is thus plainly seen that the majority of our cases belong to the advanced and far advanced classes.

Fifty-seven cases were classed as pure tuberculosis, or minor degrees of mixed infection. Of these, one, or two per cent., died; five, or nine per cent., were unimproved; 36, or 63 per cent., were improved, and 15, or 26 per cent., were clinically cured.

Thirteen were cases of marked mixed infection, with an average daily maximum temperature of 100 or over. Of these, two, or 15 per cent., died; seven, or 54 per cent., were unimproved; three, or 23 per cent., were improved, and one, or eight per cent., were clinically cured. This exemplifies what I have tried to make clear in previous papers, that climate, like everything else, is practically powerless in severe mixed infection. It is yet too early to estimate the effect in this class of cases of a potent streptococcic serum, but that it will not be great I feel quite sure, for it must indeed be a wonderful serum that will meet the exceedingly varied infections of pulmonary tuberculosis.

In eight, or nine per cent. of our patients a complication occurred, such as a bronchopneumonia following hemorrhage, or an acute miliary tuberculosis, which either caused immediate death or ruined the prospect of cure. In the one case in which pneumothorax occurred, the patient, after two years, is still living. The total gain of weight in 70 patients was 1,035 pounds, an average of 14 pounds each. Three patients relapsed after apparent cure, though one of these subsequently recovered. Marked indiscretion accounts for these relapses, and the same is true of nine patients who relapsed after improvement. The cases were under observation an average of 7.6 months, and an average of 5.1 months in the institution.

One cannot, of course, form an opinion of the value of climate in phthisiotherapy from so short a series of cases as those described in this report, but based upon my experience at Fort Bayard and elsewhere, as well as at St. Joseph's, I have certain opinions on this subject, which, it seems to me, worth while to state. There is, of course, nothing actually specific in climatic treatment, but that there is something inhibitory to the progress of pulmonary tuberculosis in high, dry climates I do not for a moment doubt. Following the change from home conditions, climatic and otherwise, to an entirely new environment, there is such a stimulation of metabolism that the patient is often at once started upon the road to recovery. No one, I think, will care to maintain that it is not easier to practice phthisiotherapy under climatic conditions which permit us to keep patients out of doors all the year round in comfort, and that without any special provision for the purpose or urging of the patient. In high altitudes there is a relative immunity from hemorrhage, not altogether accounted for by the quiet life. An environment which from a hygienic viewpoint is ideal, eliminates to a marked extent the intercurrent affections which so often play havoc with the consumptive. The symptomatology is all modified for the better, as evidenced by lower temperatures, absence of night sweats, chills, and diarrhea. At the present time at least proper treatment in an ideal climate is the privilege of the comparatively well-to-do. A great injustice is done to poor people by sending them far from home. Nothing is to be expected from climatic treatment in cases presenting severe mixed infection, and it is always wrong to send the acutely ill upon a long journey. Certain cases, impossible to differentiate before-hand as a rule, are not adapted to high, dry, climates. Marked cyanosis and myocardial degenerations I consider the only well-established contra-indications.

To give climate in phthisiotherapy its proper place is the special mission of our institution, and how well we fulfil our purpose will depend largely

upon the support given us by the profession. St. Joseph's will never be entirely satisfactory, either to those in immediate charge, nor to the members of the Advisory Board, until the support given us is sufficient to render us entirely independent, especially of the whims or caprices of patients. We have managed to keep the institution open and do our work for nearly three years with the small number of patients stated above, and the struggle we have made and are still making in the interests of the consumptive and of medical science entitles us, it seems to me, to a hearty cooperation from the profession at large.

FEIGNED INSANITY: MALINGERY REVEALED BY THE USE OF ETHER.[1]

BY CHARLES G. WAGNER, M.D.,
OF BINGHAMTON, N. Y.;
SUPERINTENDENT OF THE BINGHAMTON STATE HOSPITAL.

ON the morning of January 14, 1902, William H. Ennis, thirty-two years of age, a police officer in the Borough of Brooklyn, city of New York, killed his wife, Mary A. Ennis, by shooting her with a revolver. He then went to a small hotel in the neighborhood, engaged a room, went to bed and was soon asleep. An hour or two later he was arrested and lodged in jail. He was indicted by the Grand Jury for murder in the first degree, was tried in May following, convicted of the crime as charged and sentenced to death during the week beginning July 7, 1902. His case was appealed but the sentence was affirmed and December 14, 1903, was finally designated as the date of execution.

During the trial it was shown that Ennis had been a police officer for eight or nine years; that he was a hard drinker and possessed a bad temper; that he was married in November, 1900, and had boarded with his wife's mother for about four years prior to his marriage; that after his marriage he frequently came home intoxicated and was abusive in language and conduct toward his wife who finally, with her three weeks old baby, left him about four months before the commission of the crime and obtained a legal separation. A large amount of expert medical testimony was offered by the defense in the attempt to show that the accused was suffering from paranoia; that he was delusional, epileptic and demented, and that he was unable to walk on account of lateral spinal sclerosis, all of which conditions were declared absolutely incurable. Other testimony by well-known experts was offered by the prosecution to show that the accused was feigning. In court Ennis was incoherent and answered questions irrelevantly or not at all. He appeared unable to walk without assistance or to stand erect with his feet squarely on the floor. At each step as he rested his weight to some extent on the ball of his foot, a violent coarse tremor agitated the entire leg. These abnormal mental and physical phenomena Ennis exhibited throughout his trial and after conviction, on the way to the state prison at Sing Sing, N. Y., where he was confined until his execution.

From the testimony of the prison physician at Sing Sing, the warden of the prison and the keepers who came in daily contact with Ennis, it appears that throughout the following eighteen months he manifested little if any interest in his surroundings or in outside matters; rarely asked questions and when spoken to usually replied incoherently or not at all. His expression and manner impressed the prison officials as indicating dementia or imbecility, although they were somewhat suspicious that he might be feigning.

During the entire period of his incarceration Ennis was never observed standing or walking without assistance; at all times he appeared to be unable to sustain his weight with his feet squarely on the floor, but when supported on each side he could walk or drag himself along on the balls of his feet, and while doing so his legs were invariably violently agitated by the coarse tremor previously referred to. As the time for execution approached the warden of the prison, being in doubt as to Ennis' mental condition, requested the Governor to appoint a commission to examine him. Governor Odell appointed as such commission Dr. George A. Smith, medical superintendent of the Manhattan State Hospital at Central Islip, N. Y., Dr. Daniel H. Arthur, medical superintendent of the Gowanda State Hospital at Gowanda, N. Y., and the writer.

On December 1, 1903, the commission met at the prison and after careful study of the records of the case examined Ennis. The prisoner was brought from his cell by two keepers to the office of Principal Keeper Connaughton. As he entered the office he was in great agitation. His legs, and to a less degree both arms, trembled violently. He appeared unable to walk, but apparently tried to put his feet forward step by step as the officers supported him into the room. Apparently when he bore but little weight on the balls of his feet the muscular tremor of his legs became so great that he would have fallen if he had not been supported. He appeared unable to straighten his legs so as to bring his heels to the floor. When seated in a chair the tremor subsided and his mental agitation became less pronounced. The expression of his countenance was idiotic or imbecile and he appeared not to know where he was or to realize the nature of the questions that were put to him. When asked his name he made no response until the question was repeated many times, and then only when spoken to sharply, he said, "Ennis." When asked his first name, after considerable delay he said, "William." After being asked many times how old he was, he said "thirty-five," which was not correct, his age being thirty-three years. No further answers could be drawn from him during the examina-

1 Read at the annual meeting of the American Medico-Psychological Association, held at St. Louis, Mo., in June, 1904.

tion, but when asked if he had ever received any injury to his head, he nodded quickly in the affirmative and pointed to a spot on his head where an old scar was visible. When asked why he trembled he made no reply, but to the question "Are you afraid?" he immediately laughed and shook his head, as if desirous of conveying the idea that the tremor was due to disease and not to fear.

Ennis frequently laughed during the interview in an imbecile manner and almost continuously moved his lips as if whispering to himself, but no sound of speech could be heard. He continually looked about the room with a vacant stare. At the close of the examination, when removed from the office to his cell he dragged his feet in the same manner as when entering, and exhibited the same tremor of legs and arms.

On December 3, two days later, Dr. Smith, Dr. Arthur, and the writer again visited the prison and saw Ennis. He was brought into the office by two keepers. His countenance wore the same imbecile expression and his gait was unchanged, but when questioned he manifested slightly increased intelligence. He gave his name more promptly and when asked about the injury to his head, he immediately raised his hand to the vicinity of the scar and said "Doctors did that." When asked where he was, he replied, "In a hospital," and said that Doctors brought him there. He did not seem to realize that he was in prison, that he had committed a homicide, or that he had ever had a wife. His hearing was tested and found good. His pupils reacted promptly to light and distance. Reflexes were normal except the knee-jerk which was slightly increased. When shown different colored worsteds, he called red black and yellow red, but a few moments later when shown yellow again he appeared unable to say what color it was. When tested as to the taste he answered promptly and correctly when given sugar, but shook his head when asked to tell what salt, acetic acid, and bromide solutions tasted like. A variety of other tests were made and although Ennis showed somewhat more intelligence than on our first visit, he would not admit any knowledge of his crime. The examination lasted nearly two hours, after which Ennis was returned to his cell, two keepers supported him on his way to the elevator, and the same tremor of his legs was observed as when he was brought in. At this time the prison physician stated that, while visiting Ennis in his cell, he had asked him why he did not answer our questions, to which he replied that he did not know who we were and so he was not going to talk to us.

The results of our examination had thus far been to a considerable extent negative and, therefore, unsatisfactory. But owing to the contradictory character of the testimony at the trial and the irregularity of the alleged symptoms during his imprisonment, the commission were all of the opinion that Ennis was malingering, notwithstanding the absence of conclusive proof to sustain their convictions. It then occurred to the writer that an anesthetic might be of use in obtaining the desired evidence—the idea being that, if Ennis were malingering, the fact would become patent when all voluntary and purposeful action should be in abeyance. Accordingly, the commission met at the prison, December 8, for the third time. The prisoner was again examined. His expression of countenance, manner, gait and general appearance were unchanged. He was taken to the hospital operating room, placed upon the table and ether administered. He made no resistance and although his breathing was observed to be shallow he was soon apparently quite unconscious, but when taken from the table and with the assistance of two keepers made to walk he quickly revived and exhibited the same phenomena of gait, and the same expression of countenance as at the previous examinations.

In a few minutes he was again placed upon the table and ether administered until his muscular system appeared relaxed and consciousness was again apparently gone, but on being brought to his feet, although it was evident his mental faculties were somewhat clouded, his gait and countenance were unchanged. After a short delay Ennis was placed on the table for the third time. He made considerable resistance and declared he would not "take any more of that stuff," referring to the ether. Resistance was overcome and the ether administered until complete unconsciousness and thorough muscular relaxation were obtained. Just before this degree of anesthetization was reached Ennis became talkative, profane, and abusive; his voice was loud and strong, and his language coherent, forcible and expressive; whereas, previously he had talked but little and always in a low tone. While still profoundly unconscious he was lifted from the table and stood upon his feet. As consciousness began to return, with a little assistance he walked across the room without difficulty or muscular tremor, and at each step placed his foot squarely upon the floor. He walked out into the corridor to the elevator and on reaching the ground floor walked to his cell without assistance. The plea of lateral spinal sclerosis was thus disposed of.

The change in the character of Ennis' speech during anesthetization, his coherent, loud, profane language, which was evidently a near approach to his normal expression, and the elimination of the alleged spinal disease satisfied the commission that the pretense of insanity was without foundation and report was made to the Governor accordingly.

On the day following the last examination Ennis was visited by the prison physician, but he would not talk beyond saying that he was sick and wanted to sleep. The next morning, however, he was very communicative. When he

saw the prison physician approaching he immediately called out, "I had all you fellows guessing all right and you never would have caught me only for the ether." He said he had been "under an awful strain for a year and a half" and that he would "rather go to the chair than go through the same experience again." He talked freely about the murder and put the blame for the crime on his wife's mother. He talked intelligently about his whole life, admitted the crime and had no hope of escaping the electric chair. He said that no physician or lawyer had posted him on how to act or walk, but that one day while standing at his cell door, before his trial and after the alcohol was pretty well eliminated from his system, his legs trembled so much that he could not stand and keep them quiet. This trembling suggested the idea, and all that he had to do, he said, was to exaggerate the the shake somewhat and put on a "few fine touches."

The prison physician stated in a letter to the writer after the execution that Ennis proved to be quite a sensible fellow in his conversation, and that he went to the chair without showing any fear.

A NEW CASE OF CHLOROMA WITH LEUCEMIA, WITH A STUDY OF CASES REPORTED SINCE 1893.

BY GEORGE DOCK, M.D.,
AND
ALDRED SCOTT WARTHIN, M.D.,
OF ANN ARBOR, MICH.

INTRODUCTORY AND CLINICAL BY DR. DOCK.

In 1893[1] I reported a case of chloroma with an analysis of the cases then known. Including my own case there were only seventeen, but I felt justified in giving a clinical picture of the disease, and in assigning it an anatomical basis. The chief clinical features were: "The appearance, usually before the age of twenty, of anemia without evident cause, with loss of strength, dyspnea, and emaciation; hemorrhages in skin, mucous membranes (epistaxis), or internal organs (retina); rapid pulse; ocular symptoms, such as difficulty of vision, strabismus, and especially exophthalmus, without the special features of Basedow's disease and with tumor in the orbit; deafness and ringing in the ears, and tumors in the temporal regions, or in the cranium in other parts, or in other parts of the body." Besides the resemblance of the symptom-picture to that of many cases of leucemia, especially acute leucemia, three out of nine cases of chloroma, observed since leucemia was known, showed "an increase of the leucocytes, two of them an increase such as is seen usually only in leucemia." At that time leucemia was not so well known as it is now, and I felt obliged to devote considerable space to a consideration of the histology of the blood. I also discussed the position of the anatomical change in chloroma and concluded that it might better be termed lymphoma (in the sense originally used by Virchow, who gave leucemia as the first example of the lymphomatous disease) than sarcoma, lymphosarcoma, or lymphadenoma. An interesting feature of the morbid anatomy of chloroma was shown by my analysis, as it had been by some earlier writers—the "predilection of the periosteum, especially that of the head, but also fibrous tissue in general."

This article served to call renewed attention to the subject. Since then more than twenty cases have been reported, some of them with elaborate studies, though without demonstrating any essential changes in the clinical and anatomical conceptions of the disease. Recently I was fortunate enough to have another case. Like many others it could not be investigated as thoroughly as it deserved, but I have thought it might well serve as the basis of an analysis of the cases reported since my former paper was published. The anatomical study of the case has been made by my friend and colleague, Dr. A. S. Warthin, whose investigations in the anatomy and pathology of the blood-forming organs have already been so valuable.

Clinical Summary of the Case.—Weakness, anemia, headache, tinnitus, deafness, of one year's duration; loose teeth; emaciation; leucemic changes in blood; death from asthenia. L. J., aged forty-five years, farmer, Swede, admitted to the Medical Clinic, Hospital of the University of Michigan, December 1, 1903, on account of weakness and anemia. His father died at sixty-one years of age, from an acute illness; his mother died at eighty-two, of a disease characterized by difficult breathing. Patient has been married twice; has had two healthy children by each marriage. Patient was strong as a child. He had measles at six years; since then has never required a physician until the present illness. Denies venereal diseases. Was a farmer in early life; then worked in the woods and in lumber mills from 1883 to 1891; then resumed farming. He formerly used alcohol in excess; has taken none in the last year, and has also given up tobacco in the last year.

The present disease began in November, 1902, with a feeling of fatigue and dyspnea on exertion. Treatment was without benefit. For six weeks the patient was confined to bed by weakness; "his pulse could hardly be felt." In the early part of the disease he complained of pain in the left side of the head. Hearing was gradually lost, while a pounding noise, like that of a railroad train, was present. Also in the early stage the teeth became loose, without salivation or other local symptom. A change in the color of the skin was noted in the very beginning. There has been a gradual loss of weight, amounting now to twenty-five pounds. The appetite is fairly good; bowels constipated. The patient sleeps well. He complains of dyspnea only on exertion, but says he is very weak.

1 Chloroma and its Relation to Leucemia, The American Journal of the Medical Sciences, August, 1893.

Status Presens, December 2, 1903.—Man of large frame; muscles small and soft; panniculus thin. In the right axilla are three enlarged glands, the largest the size of a white bean; no other superficial glands enlarged. The expression is weary and apathetic. Deafness and seeming lack of intelligence render the examination difficult. The face is pale and sallow; the skin over the body very pale, but not sallow; over the legs and arms sallow. On the abdomen, just below the right costal margin, is a pale brownish pigmentation. There is a dark-brown line in the skin extending from the tip of the ensiform to the pubes, and an irregular brownish patch in the right lumbar region, but no pigmentation in other parts of the body. The skin in general is smooth, dry, and elastic. Over the right shoulder is a mass the size of a large orange, firm, elastic, movable under the skin, but fixed below. A smaller, softer, bilobed mass occupies a similar position on the left shoulder (lipomata?). There is no edema. The skull shows no abnormality except two scars on the left malar and left frontal regions respectively from injuries. The sclerae are very pale; pupils equal and react well. The lips are pale; there is marked *fetor ex ore;* tongue dry, pale, with thin gray coat, fissured and marked by teeth. The teeth are worn, but only a few are missing. The gums are red, slightly swollen, their edges covered with a grayish-green deposit extending from the teeth, removable by rubbing. Pharynx negative. Auscultation and percussion of lungs negative. Apex beat in the fifth intercostal space, nipple line. Dulness not enlarged. Sounds are clear, except the first in the pulmonary area, which is replaced by a long, loud, blowing murmur. Radial artery not thick nor tortuous. Pulse of moderate size, quick. Blood pressure (Riva-Rocci) 133 mm. The abdomen is below the level of the ribs; inspection and palpation negative. The spleen cannot be felt. There is marked pain on pressure over sternum and tibiæ.

Urine. No albumin or sugar; few leucocytes; many cylindroids. Owing to the patient's lack of intelligence and his unexpected death the urine examination was not complete. Albumose tests not made.

Blood. Pale and watery; fresh drop shows few red cells, varying in size and shape; leucocytes increased. Red blood corpuscles 509,600, leucocytes 35,669, hemoglobin 15 per cent. For differential count see below.

December 5. Examination of stool (Dr. Dock); large and formed; good digestion; no blood, pus, or mucus; no protozoa or ova. Three test breakfasts were given (one Boas') and examined. All showed absence of acid, slight excess of mucus, little or no peptic digestion (Mett.). The temperature ranged between 98° and 102.5° F., pulse 94 to 108, respiration 18 to 26.

December 8. Became restless in the night. Skin cold; delirium; refused nourishment, temperature, 96° F.; pulse, 100; respiration, 28.

Ophthalmoscopic Examination (Dr. Carrow).—Numerous hemorrhages in both retinæ; vision much impaired.

Subcutaneous injection of physiologic salt solution at 10:37 to 10:50 A.M., 12 ounces. Riva-Rocci 108 at beginning, 100 at end. Pulse weaker. Died 11:28 A.M.

The blood was stained with hematoxylin and eosin, Ehrlich's triacid, and Wright's stains.

EXAMINATION OF THE BLOOD. DIFFERENTIAL COUNTS.

Date.	Red blood cells.	Leucocytes.	Hemoglobin.	Normoblasts.	Megaloblasts, degenerated.	Free nuclei.	Small lympho cytes.	Large lympho cytes.	Lymphocytes, marrow.	Polynuclear.	Eosinophile, polynuclear.	Eosinophile, mononuclear.	Myelocytes.	Transition and mononuclear.	Basophile.
December 3	509,600	35,669	15	...	1	...	6.7	3.9	79.9	7.4	0.8	...	0.4	...	...
December 4	.....	.....	...	...	...	1.8	6.9	5.3	79.6	5.7	0.3	0.1	0.2	...	...
December 6	.....	.....	...	1	...	...	5.8	5.0	82.6	5.6	0.2	...	0.1	0.5	...
December 8	820,000	.....	15	1	...	...	2.5	2.3	81.6	7.4	2.0	0.2	1.9	1.3	0.4

The counts given are all taken from Wright's stains, which correspond closely to the hematoxylin and eosin counts. The triacid was used only to confirm the neutrophile myelocytes. The blood shows very few nucleated red cells, almost all normoblasts. The only megaloblasts found had degenerated nuclei.

In all the preparations of one day, December 4, there are many "free nuclei," up to 18 per 1000 leucocytes. At other times these are too few to count. They are very small, stain intensely, and show no protoplasm. The small lymphocytes are unusually typical, but some of them show slight fragmentation of the nucleus. There is a small proportion of typical large lymphocytes, some of which also show fragmentation of the nucleus. These two groups together are only slightly increased above normal.

From 79.6 to 82.6 per cent. of all the leucocytes differ from typical lymphocytes, but resemble these cells in certain respects, and differ still more from other normal leucocytes. They closely resemble the undifferentiated lymphocytes of the bone-marrow, and for convenience I class them in the table "marrow lymphocytes." They

range from the diameter of a red blood corpuscle to two or more times that size. They are often oval or even broadly spindle shaped. Many of them have no visible protoplasm. Others show a narrow, crescentic, or annular rim, and still others a wider protoplasm up to an amount usual in large mononuclear cells of normal blood. In most cells of this class the nucleus is round or oval, almost or quite filling the cell. In some the nuclei are reniform, or more or less incised on one side, or sometimes bilobed. Sometimes the two lobes partly overlap; sometimes they are partly or quite separated. When there are two nuclei these are sometimes unequal. The nuclei stain moderately well with hematoxylin and methylene blue; faintly with triacid. They look unevenly blurred in many cases, but in general stain like the nuclei of large lymphocytes, and marked failure to take the stain and other evidences of degeneration, so often seen in leucemic blood, are unusual. The protoplasm usually takes a blue with Wright's stain, sometimes darker than the nucleus, without granulation, but often with a spongy or reticulated appearance. Triacid stains it a pale pink or not at all. Eosin can be almost entirely washed out, but sometimes leaves a pale pink, and in some cells stained with hematoxylin and eosin the protoplasm of these cells has a pale blue tint. The protoplasm is sometimes ragged at the edges; sometimes there are few or many knob-like processes on the edges, stained a pale blue, and having a smooth, homogenous appearance. These cells cannot be separated readily from those classed large mononuclear, so far as general appearance is concerned. The distinction here is based upon the different appearance of the protoplasm and the relatively smaller and more distinct nuclei in the large mononuclears. While those classed as marrow lymphocytes, as well as the large mononuclears, have no granulations in the protoplasms, there are a few cells having the general shape and proportions of large mononuclears that show a few eosinophile granulations, sometimes very small ones, scattered over a pale and sometimes vacuolated protoplasm.

The polynuclear cells vary much in size, nuclear structure, and protoplasm, resembling in their polymorphism the polynuclears of mixed-celled leucemia. In size they vary from one to four times the diameter of a red blood cell. The nucleus is sometimes in separate parts, especially in the larger cells. The nuclei stain deeply as a rule, but the large ones show a reticulated structure with thickening at the nodal points. The protoplasm shows, with proper stains, a fine, or in rare cases somewhat coarse, acidophile or neutrophile granulation. A few of the smaller cells of this group are probably Ehrlich's pseudo-lymphocytes.

The polynuclear eosinophiles, relatively rather low, but absolutely within normal limits, show no marked abnormalities in size or structure. Many have nuclei less polymorphous than in normal blood, but still within the range of variation in such cells in general.

Mononuclear eosinophiles were present only two days out of four in small proportion. Most of them are large, but some are about the size of red blood corpuscles. In some the protoplasm is very narrow. I have counted among the eosinophile cells some that have very few granules, as mentioned above. In one cell, not included in any of the counts, a "marrow lymphocyte" without protoplasm, there were ten large eosinophile granules scattered over the cell without any explanation by way of artefact.

The myelocytes (neutrophile) vary in the usual manner from small to large. Some of them have vacuoles in the protoplasm.

Basophiles appeared only on the last day. They all have round or elliptic, excentric nuclei. Some are small, some large.

The red blood corpuscles show slight changes, aside from their very scanty number. The cells vary somewhat in size, but marked departures in size and shape are not present. The cells take the usual stains well; they show very little polychromatophilia. Normoblasts are few. No typical megaloblasts are to be found, but some of the large nucleated red corpuscles have trefoil or irregular nuclei.

During the patient's lifetime the full details of the blood were not known, but I had carried the examinations far enough to show that while the blood resembled in general that in many cases of acute leucemia it had some important differences in the details of the cells as well as in the differential count. It was more polymorphous than is usual in acute lymphocythemia, and resembled somewhat closely the blood of a case of acute lymphocythemia with extensive intestinal lesions that I had studied a short time before, and a report of which will be made by Dr. Warthin.

The diagnosis, as made at a clinical conference December 4, was: acute leucemia, possibly lymphocythemia, in the late stage of a severe anemia of unknown cause. The points of resemblance, and of difference as compared with pernicious anemia with late lymphocytosis, were brought out. Chloroma did not then seem as probable as acute lymphocythemia with lesions in the alimentary tract, but before the autopsy, on account of the absence of distinct gastrointestinal symptoms while under observations, I thought chloroma was more probable, notwithstanding the absence of the peculiar head symptoms.

Permission to make an autopsy was obtained with great difficulty and after much loss of time. It was impossible to examine the head, and owing to lack of time the examination of the other bones was seriously limited.

Autopsy protocol. December 9, 1903, 10 A.M. (Dr. Warthin.) Body well built. No deformities or anomalies. Length 160 cm. Abdomen on level of ribs. Left side of thorax not as full as right. Musculature fair; muscles in fair con-

dition. Rigor mortis marked, present throughout. Panniculus moderate. Slight edema over ankles. Body heat entirely absent. No signs of decomposition.

Skin is very pale on the whole. There is pale red hypostasis over the back. The flexor surfaces of both upper and lower extremities show no unusual pigmentation. Over the upper portion of the right thigh there is an area about the size of a hand showing scattered spots of pale-brownish pigmentation. In the median line of the abdomen there is a pale linea fusca. The wrists and back of hands are tanned. Over the inner side of the right elbow there is a small ecchymosis, and numerous small petechial hemorrhages are scattered over the flexor surfaces of both upper and lower extremities being most marked over the left arm and less numerous over the lower extremities. Transfusion mark in right pectoral region. The hair is thin over the vertex, and harsh and dry. The beard is slightly gray. The teeth are in fair condition.

Over the outer third of the left clavicle there is a subcutaneous tumor 7 cm. long by 5 cm. wide. It is slightly lobulated and at its lower pole there is a smaller mass 2 cm. in diameter. The tumor is freely movable, is not adherent to the skin, is semielastic. Over the outer third of the right clavicle there is a similar roundish tumor 7 cm. long by 6 cm. wide. It is firmer in consistency and is less freely movable than the growth on the left. It is not adherent to the skin and does not seem to be attached to the periosteum. It does not move with the arm. Both tumors present the characteristic of lipomata.

The axillary glands are palpable, but not enlarged. Cervical glands not enlarged. The inguinal glands are just palpable, not enlarged.

The head was not opened. (No permission.)

On section the muscles are pale brownish-red; panniculus a pale lemon-yellow.

The diaphragm is at the fourth intercostal space on the right, and at the fifth rib on the left. The first costal cartilages are ossified.

On removing the sternum its inner surface is found to be covered with a dense infiltration about 1 cm. thick and having a distinct light grass-green color. The infiltration is most marked over the upper part of the sternum and here the color is more decidedly greenish. The sternum is softer and more friable than normal, and is easily fractured or cut. The sternal marrow is hyperplastic, pyoid in character, and has a slight greenish tinge. Exposure to the air and slight drying caused the green color of both the infiltration and marrow to become more marked.

The mediastinal fat is of fair amount, and of a pale lemon-yellow color. Contains a few small pale lymph nodes. In the thymus fat there are several large lymphoid structures, one of which is about the size of an English walnut and has a greenish-gray color. On section it is very edematous, medullary in consistency, greenish-gray, and showing fine lines of anthracosis. The other lymphoid structures in this region are soft, grayish, edematous, and more or less anthracosed.

The apex of the heart lies in the fifth intercostal space half-way between the left paresternal and nipple lines. The heart extends four finger-breadths to the right of the median line. No fluid in either pleural sac.

The pericardium is distended. Contains 40 c.c. of clear fluid, the increased intrapericardial tension being due to dilatation of the heart.

The heart is much enlarged, the enlargement being due chiefly to dilatation of the auricles. Weighs about 700 grams. On the anterior wall of the right ventricle there is a large, triangular, tendinous spot measuring 5 x 5 x 4 cm. Near the apex of the left ventricle there is a smaller one measuring 2 x 1 cm. Smaller ones on the posterior wall of the right ventricle. The subepicardial fat is increased in amount and is of a pale lemon-yellow color, translucent, and edematous. Everywhere over the surface of the heart along the course of the smaller vessels there are great numbers of small, punctate hemorrhages. They are most numerous on the posterior wall near the apex. Coronary veins greatly distended. The auricles contain pale plum-colored blood and large white clots. The walls of both ventricles are lined with similar white clots. The mitral and tricuspid orifices are dilated. The heart muscle is pale and soft.

The left lung weighs 1,000 grams and measures 28 x 18 x 6. Pleura adherent posteriorly and over base by old and rather tough adhesions. The lung is voluminous, pale grayish-pink above, and moderately hypostatic posteriorly. On section it is very edematous, yielding an abundant foamy exudate on slight pressure. Very small, whitish, airless areas throughout. Anthracosis moderate.

The right lung weighs 1,120 grams and measures 30 x 18 x 6. Adherent posteriorly and over the base by very firm adhesions. Pleura covered with the remains of old adhesions. Lung very voluminous. Color similar to that of left lung. Consistency somewhat more firm than that of left lung and the cut surface is darker in color, otherwise similar. The small, whitish, airless areas are more numerous in lower lobe.

The pulmonary veins contain large pale clots. The mucosa of the larger bronchi is pale, that of the smaller is injected. The smaller bronchi are somewhat dilated. The bronchial glands are enlarged, very pale gray, soft, and edematous. Thoracic duct negative. Thoracic and cervical esophagus negative.

No pathological changes in mouth and throat so far as could be ascertained (section not permitted). Neck organs examined from below. No pathological changes found.

No fluid in the peritoneal cavity. The omentum is rolled up; moderately rich in fat of a very pale yellow color. The lower border of the stomach extends one finger-breadth below the umbilicus. The lower edge of the liver in the median

line is four finger-breadths below the ensiform and one finger-breadth below the edge of the ribs in the right nipple line. The pylorus is four finger-breadths to the right of the median line. The colon is contracted, filled with hard, fecal masses. The duodenum is moderately dilated; the remaining portion of the small intestine is collapsed. The appendix is very long and large, the distal one-third dilated. The greater part of the appendix lies in the pelvis and is attached to the sigmoid flexure by recent adhesions, which are very vascular. The peritoneum about the appendix is thickened. No evidences of any perforation, old or recent.

The spleen weighs 426 grams and measures 17 x 11½ x 5 cm. It is rather soft and flattens on pressure. The capsule is slightly thickened and over it there are scattered small hyaline tags. There are four distinct notches on the anterior border. On section the pulp is pale red, soft, swells up above the stroma, and is easily scraped away. The stroma is covered up by the hyperplastic pulp. The follicles are very few and small, and can be seen only in a few places near the capsule. The cut surface presents a moderately shagreened appearance and is of a uniform pale red.

The left adrenal is very small, completely surrounded by pale-yellow fat. On section it shows no change. The right adrenal is likewise very small and embedded in a thick capsule of pale fat. On section shows post-mortem change of the medulla, otherwise negative.

The left kidney has a very thick fatty capsule of a pale lemon-yellow. The fibrous capsule is stripped with some difficulty. The organ freed from its capsules weighs 190 grams and measures 14 x 6½ x 3½ cm. The cortical surface is very pale and slightly granular. Traces of the fetal lobulations are present. The cut surface is very pale and cloudy. The outlines between the labyrinths and medullary rays are not distinct. The consistency is somewhat diminished. The pelvis presents no pathologic changes. The subpelvic fat is very abundant.

The fat and fibrous capsules of the right kidney are similar to those of the left. The stripped kidney weighs 190 grams and measures 17½ x 7 x 3 cm. The organ contains more blood than the left, the outlines between the medullary rays and the labyrinths being more distinct. Scattered over the cortical surface are small, slightly elevated, pale yellowish or grayish spots about 2 mm. in diameter. On section these spots are nearly round and are located for the greater part just beneath the cortical surface. They are fairly firm and are not affected by pressure. When scraped with the point of the knife they yield an abundance of cells. In other respects the appearances resemble those seen in the left kidney.

The ureters are dilated and filled with slightly turbid urine. The bladder is greatly distended and filled with slightly turbid urine. Its wall is thin, and the mucosa very pale. No other changes.

(The stomach was ligatured at the cardiac orifice and removed in connection with the intestines, which were ligatured at the rectum. The contents were preserved for chemical examination.) The stomach is dilated, its wall thin, and the mucosa very pale. Lymphoid follicles prominent. In the submucosa of the fundus there is a small round tumor about the size of a pigeon's egg. The mucosa is intact over the growth, which has a firm consistency.

The intestines are very pale. The lymphoid structures are rather prominent, but not distinctly enlarged.

The liver weighs 2,230 grams; its greatest measurements are 29 x 20 x 11 cm. The general color of the organ is a light yellowish-brown. Over the surface and just beneath the capsule there are many small, yellowish or whitish spots. On section these spots extend a short distance into the liver substance, so that they appear as round or oval areas about 2 to 4 mm. in diameter. They are sharply circumscribed, fairly firm, but yield an abundance of cells on scraping with the point of the knife. Besides these small spots there are seen underneath the capsule larger pale areas, less sharply circumscribed, and of a more reddish-yellow color. On section these areas also extend into the liver and appear to be made up of groups of liver lobules that have suffered some parenchymatous change. On the main section a narrow strip of liver lobules showing characteristic nutmeg appearance is found just beneath the capsule. The remaining portion of the organ is very anemic, the central veins empty, and the lobules small and of a light chocolate color. Similar small, yellowish areas to those seen underneath the capsule are scattered over the surface.

The gall-bladder is adherent to the omentum. It is moderately filled with dark greenish-brown bile. No stones or sand. Bile passages patent. Examination of portal vein is negative.

The pancreas is about normal size, very pale, and somewhat softer than normal. Section negative.

The mesenteric lymph glands are slightly enlarged, pale and soft. The lymph glands of the portal fissure are very large, pale, soft, and homogeneous on section. The retroperitoneal glands are moderately enlarged, very pale, and of medullary consistency. The hemolymph nodes are pale, but present no other gross changes. No greenish color seen in any of the abdominal or retroperitoneal lymph glands.

The examination of the sexual organs, internal and external, is entirely negative.

On stripping back the prevertebral tissues the bodies of the vertebræ are found to be covered with flattened greenish masses varying from 4 to 10 mm. in thickness. Over the intervertebral disks the greenish color barely shows, so that the greenish vertebræ are sharply outlined from each other by the whitish disks. In the lumbar region the color is most marked over the bodies, but in the thoracic region the greenish tissue is more

marked along the sides of the vertebræ. The greenish tissue extends for a short distance over the ribs. It also infiltrates to some extent the prevertebral fat-tissue. A thin layer of the greenish tissue is found in both iliac fossæ and over the inner side of the sacrum. It is not present on the clavicles or on the long bones of the lower extremities. The bodies of the vertebræ are very soft and are easily cut with the cartilage knife. The marrow spaces are increased in size and the bony trabeculæ greatly rarefied. The red marrow is entirely replaced by a grayish pyoid marrow having a distinct green color. After exposure to the air and drying, the grass-green color became more marked. On cutting into the vertebra, direct connection can be seen in many places between the greenish tissue surrounding the vertebral bodies and the greenish marrow of the enlarged marrow spaces. The greenish tissue is firmly adherent to the surface of the vertebræ and cannot be stripped from it.

Careful and thorough examination of the head fails to reveal any evidences of periosteal thickening. There is no sign of the presence of orbital growths.

(The dorsal and lumbar portions of the spinal cord were removed.) Cord and meninges present no pathologic appearances. The bony wall of the canal is covered with a thin layer of greenish tissue.

The right tibia is split. Its fatty marrow is partly replaced by marrow redder than that found in either the sternum or vertebræ, but small points of pyoid, greenish-gray marrow are also present.

The section of the growths on the right and left clavicles shows that these are subcutaneous tumors having all the gross characteristics of lipomata.

Anatomical Diagnosis. The character and location of the greenish growths in connection with the changes in the red marrow form a sufficient basis for the diagnosis of chloroma.

(To be Continued.)

COMPLICATIONS OF DIPHTHERIA; WITH SUGGESTIONS FOR THE FEEDING, MEDICINAL AND HYGIENIC TREATMENT.

BY LOUIS FISCHER, M.D.,

OF NEW YORK;

VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS, ETC.

The Stomach.—The first effect of a diphtheritic toxemia is manifested on the stomach. We know that the diphtheritic toxin seems to inhibit the production of hydrochloric acid. Behring's theory is that the cells and the cell elements are disturbed in their activity by the action of the toxin and that the antitoxin stimulates their activity. The truth of this statement must be admitted when we compare what can easily be proven experimentally, that twenty-four to twenty-eight hours after the injection of antitoxin, hydrochloric acid was again present in the gastric juice.

Large Dose Required.—The question of dosage is important enough to consider in this connection. I have frequently found that a dose of 5,000 units was *not sufficient* in a severe case of septic diphtheria. When a second dose of 5,000 units was given no improvement was noted until twelve hours later, so the third dose of 5,000 units was given twenty-four hours later. Ten thousand units can be given in twenty-four hours, and even more, if necessary. I have come to look upon the employment of antitoxin in the same light as when an active drug is to be given. Take for example the effect of belladonna on the system. This drug will frequently be inert until its physiological effect is produced. One child will show its physiological effect after a very small dose of belladonna, while another child, more robust, can tolerate three times the dose to produce the same symptoms.

Feeding.—This has an important bearing on the prognosis of a case of malignant diphtheria. Knowing the effect of the diphtheritic poison, it is imperative to sustain the system by proper feeding. As there is a decrease in the quantity of hydrochloric acid secreted we must allow for this in ordinary food. An infant should be given one to five drops of diluted hydrochloric acid after its feeding, and if digestion is not improved, we must resort to predigested milk food consisting of peptonized milk.

When bottle-feeding or cup-feeding is unsuccessful, or when children refuse food, gavage should be remembered. Gavage through the nose is the plan of feeding very rarely used at the Willard Parker Hospital. In some cases the Casselbery method of feeding has served me very well. When vomiting is provoked by gavage and the tube is coughed out, I have frequently resorted to spraying the pharynx with a three per cent. cocaine spray several minutes before the time for feeding. When this method does not relieve the nausea and vomiting, absolute rest of the stomach is indicated, and we must resort to rectal feeding. Rectal alimentation should be given only by a trained nurse or by the physician himself. I have had excellent results in the feeding of intubated cases by rectal alimentation when the same was carried out by one who was competent. The rectum and colon are first washed clean by means of soap water. After the fecas are washed away I usually instruct the nurse to wait one-half hour, and then inject two or three ounces of the following:

℞ Yolk of egg..... 1 yolk.
Starch water..... 2 ounces.
Fairchild's peptonizing powder, 1 tube.
Salt ..... A pinch.

Mix thoroughly and inject slowly into the colon through a funnel to which a soft rubber catheter is attached. These injections may be repeated every four hours.

Nasal Cases.—In nasal diphtheria very high fever frequently persists. Great relief is afforded

by irrigating the nose and removing these membranous plugs. Septic infection will persist until the nose is thoroughly cleaned. The ease with which a membranous patch will extend upwards from the posterior pharyngeal wall should be remembered when determining on a plan of treatment. When the membrane exfoliates it will result in serious impediment to the entrance of oxygen. Mechanical treatment by means of normal saline solution will wash away these septic plugs and relieve obstruction to the entrance of air. Attention to the nose is more important in diphtheria than in any other disease. My rule has been to wash the nose with a weak permanganate of potash solution, or normal saline solution, *whether the case has a tube in the larynx or not.* My experience has been so good in tube cases that I do not *hesitate to advocate the use of nasal washing in every case of diphtheria* as a routine measure. Toxic substances can be more directly eliminated in this manner than by any other means.

Enlarged Lymphatic Glands.—I have frequently seen enlarged lymphatic glands greatly improve during the course of diphtheria when these necrotic patches were removed from the nose by cleansing. I believe that the same holds good in the treatment of lymphadenitis cervicalis and in scarlet fever.

Feeding.—When the appetite is so poor that milk will be refused, especially during acute febrile attacks, the curd should be removed from the milk by making junket and straining the same. Whey can be given in small quantities more often than milk containing the curd. Vegetable proteids can be fed in the form of soup made from split peas or lentils, or in the form of almond milk made by macerating almonds with water.

The Bowels.—Next in importance is the *elimination of poison through the bowels.* The treatment of diphtheria in children would always be commenced by producing active catharsis. The frequency with which pseudomembranes and infected secretions are swallowed shows the importance of this treatment. Children rarely, infants never, expectorate—they invariably swallow the loosened membranes. By producing liquid stools we eliminate toxins and thereby reduce the amount of toxemia. The best drug for cleansing the intestine is undoubtedly calomel. It is best administered by giving a large dose followed by repeated small doses. Salines are also advised. Vomiting will sometimes be produced after the administration of calomel; if so, then vegetable cathartics such as elaterin or podophyllin in 1-10 gr. doses or more should be tried. This active catharsis should be continued during the whole course of treatment, or until convalescence is established. We need not fear to deplete the body by this active cleansing, especially if we aid the volume of blood by introducing normal saline solution, as I shall describe later.

The Heart.—Next in importance to the conditions previously outlined is the effect of the toxin on the heart. When this condition is encountered great skill will be necessary to guide the patient to a successful recovery.

A study of the pathology of this disease will show the destructive effect of the toxins in the system. The retention of these poisons in the blood is a danger. Such danger consists in the development of *toxic myocarditis,* and unless the poison is eliminated, death may result. The toxin can be eliminated chiefly through the kidneys, skin and bowels.

Toxic Myocarditis.—Just as we treat the general toxemia by elimination through the skin by subcutaneous injections of hot water, through the bowels by catharsis, and through the kidneys with active diuresis, or by injecting hot saline solution into the colon, the destructive tendency of the toxin must be borne in mind if we wish to avoid death. We must remember that unless very vigorous treatment is instituted paralysis is possible, if the patient recovers.

Sustain the Heart.—The feeble condition of the heart's action requires active stimulation. Alcoholic stimulation by means of whisky, or better yet, by champagne, liberally administered, is of prime importance. I have frequently given one or two pints of champagne in twenty-four hours, in doses of one wineglassful every hour or oftener. Into the champagne strychnine can be given, 1-60 of a grain, every hour to a child one year old. Whisky should be administered freely, two or three teaspoonfuls well diluted can be given every hour, combined with strychnine.

We must not fear giving heroic doses, for it is only by heroic treatment that we can win in a deep-seated case of septic diphtheria. Tincture of musk in two to five minum doses every hour is valuable. The musk must be pure Tonquin musk. Hot coffee, into which small doses, 1-10 to 1-5 of a grain of sparteine is given, can be repeated every two or three hours.

Hypodermic Medication.—Several pints of normal saline solution are given first choice. The injection of ten to fifteen drops of spirits of camphor or camphorated oil will frequently have a toning effect on a weakened heart.

Throat and Lungs.—The treatment outlined for the relief of a general toxemia applies equally well, although indirectly, to the care required by the respiratory apparatus. Stenosis of the larynx demands the usual operative treatment, namely, intubation. One important point is essential, *i.e.*, that we admit all the fresh air possible to oxygenate the lungs. When we are dealing with crowded apartments and unsanitary surroundings, then pure oxygen should always be given. I make it a rule to exclude all the family from the sick-room, excepting the trained nurse, the mother, and father. To permit friends or several members of the family to go in and out of the sick-room is simply robbing the patient of oxygen in his struggle against death.

Position.—The semirecumbent position should be remembered to guard against hypostatic congestion of the lungs. Pneumonia, if present, must not necessarily be looked upon as a fatal complication. I have seen many cases get well both in hospital and private practice.

Local Treatment of Pneumonia.—The application of dry cups, three or more over the affected area, or a sinapism, to be repeated in twenty-four hours, will frequently relieve dyspnea or interference with breathing. This will also be valuable when cyanosis exists. Carbonate of ammonia is one of the best diffusible stimulants, and should be remembered in the pulmonary complications of diphtheria. It can be given in doses of one to five grains with or without a stimulant, repeated every hour until its systemic effect is apparent.

Hypodermoclysis.—Sometimes saline colon enemata are too difficult to manage, owing to lack of assistance or an uncontrollable child. When a child has a tube in its larynx for the relief of croup it may be advisable to avoid struggling, owing to the danger of excitement and the probable coughing up of the tube. At such times the hypodermic injection in the loose cellular tissue of the abdomen of a pint or more of hot saline solution will be equally well absorbed. For the latter method a long aspirating needle can be attached to a fountain syringe.

Nephritis.—In every case of toxemia, systematic examination of the urine is demanded. The quantity of urine should be noted for the reason above stated, that the glands of the body do not functionate properly. A specimen of urine should be procured and centrifuged. The sediment should then be examined microscopically for the presence of casts. The chemical examination should be made to determine the presence of albumin and blood. I do not lay much stress on the latter, but rely chiefly on the microscopical result. Active diuresis is demanded so that the system is drained of its poison through the kidneys. One of the best drugs to stimulate the kidney is strychnine. Another drug used to advantage is nitroglycerin. When scanty urine exists, then diuretin in doses of three to fifteen grains, three or more times a day should be tried. If vomiting or other gastric disturbances exist then diuretin in ten to fifteen-grain doses can be put into a suppository and administered per rectum. Sweet spirits of niter is a useful stimulant and diuretic in doses of ten to fifty drops every hour or two, as the exigency of the case required. Alcoholic stimulation, such as champagne, is not contraindicated even though nephritis exists.

Indications for the Introduction of Liquids into the Body.—What has previously been said in regard to the inactivity of the glands of the stomach applies equally well to the kidneys. The toxin paralyzes the secretory and excretory functions. It behooves us, therefore, to aid these functions by proper stimulation, hence large quantities of liquids are demanded. I have previously mentioned the necessity of warm saline solutions. The same can be introduced by means of a soft flexible colon tube or a rubber catheter attached to a fountain syringe. The temperature of the saline solution should be at least 115° to 120° F. When this is introduced slowly and the child becomes accustomed to the presence of the catheter it is not difficult to introduce several pints of hot salt water. This can be repeated every three or four hours, depending on the result following the injection. The pulse should show more regularity and usually more tension will be noted. The heart's action should be stronger and the heart sounds clearer.

A few facts of decided clinical importance have been noted by me at the bedside in the hospital: First, that *the temperature alone is not a sure guide as to the outcome of a case of diphtheria. Second, that the heart is the guide, hence a study of the pulse is more important in estimating the prognosis of a case of diphtheria.*

UNCINARIASIS AS SEEN IN NORTH CAROLINA; ITS FREQUENCY, ETIOLOGY, PATHOLOGICAL SIGNIFICANCE, SYMPTOMS AND TREATMENT.[1]

BY J. L. NICHOLSON, M.D.,
OF RICHLANDS, ONSLOW CO., N. C.,
AND
WATSON S. RANKIN, M.D.,
OF WAKE FOREST, N. C.;
PROFESSOR OF PATHOLOGY, WAKE FOREST COLLEGE.

INTRODUCTORY:

My attention was attracted to this interesting and important malady by a case admited to the Maryland University Hospital, June, 1903, where I was then resident pathologist. This case was sent in from the dispensary, diagnosed malaria. Blood was negative, and showed absence of Widal. Differential leucocyte count showed an eosinophlia of 11 per cent. Stool examination by Dr. Wm. I. Mesick and myself resulted in diagnosis of uncinariasis, a diagnosis which Dr. Stiles kindly confirmed for us. So far as I can find recorded, this is the first case ever diagnosed in above hospital, and the fourth case recognized in Maryland.

Having become interested, I collected most of the American literature bearing on the subject, and on reading this literature, was very much impressed by the apparently exaggerated claims of every single investigator of the disease on the one hand, and on the other hand by the non-acceptance of these claims by the general profession, as manifested by the small number of cases and the scanty literature.

Hear some of these claims: Dr. Stiles says, "There is in fact, not the slightest room for doubt, that uncinariasis is one of the most important diseases of this part of the South. In

[1] Part of paper was read before the North Carolina Medical Association, Raleigh, N. C., May 23, 1904.

frequency it belongs in the general class with malaria, tuberculosis and gonorrhea." He was writing from South Carolina. Dr. H. F. Harris, of Atlanta, says: "The most common of the severe diseases of the South." Dr. Bentley K. Ashford, Assistant Surgeon, U. S. Army, from Porto Rico, writes: "This disease is the most destructive and general disease of Porto Rico."

Now add to this the unqualified endorsement of every single investigator of this disease, and you have one side of the question.

Let us now see the other side: The first case definitely recognized in this country was by Blickhahn, of St. Louis, in 1893. Up to January, 1900, there was only seven cases in American literature. In January, 1903, Dr. Capps, of Chicago, could collect only fifty-one cases in American literature, and since then the number has been increased, so that now we can find about 160 or 170 cases. So from these facts, we find an ignorance or skepticism concerning the importance of above claims, making the question one with two sides, at once becoming interesting and inviting to investigation.

My position as resident pathologist to the above institution expired in June, 1903, and in July I located in Onslow County, N. C., a sandy, warm country. I had not been there long before I encountered several cases. Then it was my good fortune to meet Dr. J. L. Nicholson, for whom I diagnosed microscopically several other cases. We were at once impressed with the great frequency of the disease, and realizing the truth of the above claims, and also that the disease was not attracting the attention in North Carolina that its frequency and importance deserved, we decided to investigate it as far as our means and time would allow. The primary object of the investigation was to show the frequency, and secondarily to learn what we could concerning the etiology, symptoms and treatment. Our plan of work was greatly facilitated when I was called to the chair of Pathology at Wake Forest College in September, 1903.

Plan of Investigation.—In October we proposed a canvass among the doctors of different counties scattered in various sections of the State, to the State Board of Health, provided they pay our expenses. The offer was accepted and the Board of Health had printed a number of circular letters, one of which was mailed to each doctor in a county together with a personal appeal, asking the doctor to collect stools from patients suffering with symptoms of uncinariasis. In the letter we also stated that we would visit the doctor's office in about ten days and with a microscope which we carried with us, we would examine all the stools collected, free of charge. One week of this work, in the latter part of December, proved very discouraging. Many of the doctors had not collected a single specimen, and only a few had collected one specimen. In the whole week's work, only four cases were found. Returning to Wake Forest, I began an examination of students, examining *all* the students from one county, before starting on a new county. We have kept etiological records (blanks) of all our cases. In these records the mode of conveyance is especially gone into, particular attention being paid to dirt-eating, drinking water and ground-itch. In all we have diagnosed and studied 147 cases since September and the contents of this paper is based upon a study of these cases. We shall ask pardon for the repetition of parts of the subject already gone into in other journals, in order that we may preserve the continuity of our theme.

Historical.—Our oldest reference to a disease which was most probable uncinariasis, is contained in an old Egyptian papyrus, thirty-five hundred years old. Here a disease is described whose clinical features are those of uncinariasis. It is further stated that patients suffering from this disease frequently pass worms, a supposed effect of the disease. The next references occur in the seventeenth and eighteenth centuries, when Piso, of Brazil, in 1648, Labat, of Guadeloupe, in 1742-1748, Chevalier, of San Domingo, in 1752, Dazille and Bason, of the Antilles, in 1776, and, lastly, Edwards, of Jamaica, in 1793, referred to a disease with an anemia of this special type. In Europe the disease was first discovered among the miners of Ansin in 1802. The special cause of the European type was discovered by Dubini, of Milan, Italy, in 1843.

In this country our earliest references to a disease which was almost surely uncinariasis is contained in certain records, which refer to an anemia associated with dirt-eating. To the credit of North Carolina, it may be said that the oldest of these records is from Dr. Pitt, occurring in 1808, who describes this clinical condition in dirt-eaters along the Roanoke River. Following this is Chabert's description of a similar condition among the slaves of Louisiana, then Jordan's of Person County, N. C., description of negro consumption. Then Cottling's, of Richmond County, Ga., in 1836. Little, of the pine barrens of Georgia, and La Conte, Florida, both these last in 1846, and finally Duncan, in 1850, in St. Mary's Parish, La., all describe a condition exactly corresponding to clinical uncinariasis as we now know it.

In 1864, Dr. Ferdinand Herff, of San Antonio, Tex., performed an autopsy on a Mexican woman dying in his care, in whose intestines were found numerous small round worms, which at the time he thought were young ascarides, and he now believes were uncinaria. This is very probably our earliest pathological reference to the American type of the disease. In 1893, Blickhahn, of St. Louis, recognized as such the first case of uncinariasis diagnosed in this country. The case was that of a German, three years resident of the United States, and he most probably contracted the disease in Germany and therefore suffered the European type. This is the last we hear of the disease until 1896, when Mohleau, of Buffalo,

reports five cases, three of which were imported. No other case is recorded until Tebault, of New Orleans, adds it in 1899. This was an Italian boy who developed the disease from New Orleans. We see from this in December, 1900, there were only seven cases recorded in American literature. Then Dr. Bailey K. Ashford records four cases, all imported from Porto Rico. To Dr. Ashford belongs the credit of first seriously directing attention of Americans to this disease. Dyer, in St. Louis, adds another case in March, 1901. Then comes Dr. Claytor's case from Virginia, the first of American type definitely recognized by Dr. Stiles.

Allen and Behrend, from Philadelphia, report another case, imported from Italy, in July, 1901. Dr. Gray, of Richmond, reports two cases from Virginia in September, 1901. Dr. Allen J. Smith reported eight cases before the Texas Medical Society this same year. To Dr. Smith belongs the credit of pointing out the endemic occurrence of the disease. Dr. Schaeffer, of Galveston, added another case in October, 1901, which was imported from Mexico. Still another is reported by Dr. Boggs, of Pennsylvania, the same year. Dr. John L. Yates records the first autopsy on the disease where is was definitely recognized in America. This case was also the first case diagnosed in Maryland. By the end of 1901, there were about twenty-seven cases reported in Americal literature. In January, 1903, Joseph Capps reports an autopsy, and was able to collect fifty-one cases from American literature.

In 1903 Dr. Claytor's paper, before the American Medical Association, at Washington, brought out in discussion Dr. Bondurant, of Mobile, who reported fifty microscopical diagnoses from Southern Alabama, also Dr. Harrison reports three cases from Talladega, Ala. At the same time, Dr. McCaskey, of Fort Wayne, Ind., reports three cases, and Dr. Claude A. Smith, of Atlanta, Ga., said that he had diagnosed so many cases that he had ceased to record them. Then, in the November number of the *American Journal of the Medical Sciences*, Dr. Allen J. Smith reports eight cases more in detail, and in the same issue of this journal, Dr. Craig reports twelve cases occurring in returned Philippine soldiers. This is about all the cases from which we can draw conclusions. The important deductions which we obtain from this array of historical points is, that this disease of a contagious nature has lasted long enough to account for its widespread distribution and frequency.

Frequency.—This is one of the most important points to ascertain. The importance of the disease will rest chiefly, first upon its frequency and secondly its pathological significance. In order that we may have a standard of comparison, let us look at its frequency elsewhere. Since Dubini discovered the cause of the disease in 1843, it has been found in so many countries, that it is very probable that it is endemic the world over between the parallels 51° 30′ north and 30° south. In Egypt it is found in almost every cadaver. So frequent is it, that it is known as Egyptian chlorosis. In India, Manson states that in certain sections, 75 per cent. of the population is affected. In Madras 52 per cent. are affected. In Kiolo, Japan, 13 per cent. In Java, Ceylon, the Straits Settlements, and in this hemisphere, in Brazil and Guinea, it seems equally prevalent. In Porto Rico, last year, one-fourth the death rate was due to an anemia, which in all probability was due to this parasite. The government of the island of Porto Rico has recently appropriated $5,000 for the study of this disease.

Now let us come a litle nearer home and see something of its frequency and distribution in the United States. As above stated, the first case recognized in this country was that diagnosed by Blickhahn in 1893. But the interest of the profession was not aroused until Dr. Stiles brought his painstaking investigation before us in 1902. Of course it has not been studied enough yet to allow more than appropriate conclusions concerning the frequency. But we can say now, that the more the disease is studied, the greater does this frequency appear. The writer on this subject in Allbutt's system, has well said: "To diagnose the disease, one only has to suspect its presence." Its distribution in the United States is as follows:

New York: nine cases reported, seven of these imported and it is not probable that the other two were infected in the State. Pennsylvania: three cases, all imported. Maryland: four cases, all imported. Virginia: three cases, all American type. Georgia: Harris reports thirteen cases, and Claude A. Smith has seen so many that he has ceased to record them. Beside these two observers, Dr. Stiles found the disease very prevalent here. South Carolina: Dr. Stiles in his tour of investigation found sixty or seventy cases. Florida: Dr. Stiles states that it does not differ from Georgia in point of frequency. Alabama: Dr. Bondurant reports fifty cases, and Dr. Harrison three. Louisiana: One case could be found recorded. Texas: Dr. Allen J. Smith in examining the stools of eighty-six students found eight infected. Three other cases could be found recorded from this State. California: Claims fifteen cases, all imported from Philippines and Mexico. Missouri: two cases, both of which were probably imported. Indiana: three cases, all probably imported.

North Carolina.—In this State, when we began our investigation, there were only two cases recorded. These were seen by Dr. Stiles in his Southern tour of investigation. As above stated, the investigation was made by corresponding with doctors, arousing interest and securing the cooperation of a doctor wherever possible. He was asked to send specimen of stools from patients suffering from symptoms indicating uncinariasis, which group of symptoms were mentioned in enclosed circular. The second method

was by systematic examination of students in college. No selecting was done except by counties. Most of the counties from which the students were examined were from Eastern Carolina. The results are truly surprising and almost beyond our conception. In Wake Forest College there are 325 students. About 140 examinations were made and 52 cases, or 37 per cent. of those examined, were found infected. Most of them were mild cases, many without any symptoms whatever. Interesting to compare with these findings are those of Dr. Allen J. Smith, of the University of Texas. He examined the stools of 86 students and found eight cases infected.

Many of the counties showed every man infected. Here are the results of examination according to the counties, which has an important bearing on the distribution of the disease in North Carolina: Sampson Co., six men in college, all infected, 100 per cent.; Pender Co., three men in college, all infected, 100 per cent.; Iredell Co., four men in college, all infected, 100 per cent.; Columbus Co., two men in college, all infected, 100 per cent.; Cumberland Co., one man in college, infected, 100 per cent.; Chowan Co., one man in college, infected, 100 per cent.; Pasquotank Co., one man in college, infected, 100 per cent.; Washington Co., one man in college, infected, 100 per cent.; Wilks Co., one man in college, infected, 100 per cent.; Perquinnans Co., one man in college, infected, 100 per cent.; Northampton Co., one man in college, infected, 100 per cent.; Bladen Co., one man in college, infected, 100 per cent.; Martin Co., one man in college, infected, 100 per cent.; Hertford Co., sixteen men in college, fourteen examined, ten infected, 72 per cent.; Bertie Co., four men examined, two infected, 50 per cent.; Onslow Co., two men in college, one infected, 50 per cent.; Burke Co., three men in college, two infected, 66⅔ per cent.; Henderson Co., two men examined, one infected, 50 per cent.; New Hanover Co., only one man examined from this county and he was infected; Halifax Co., two men were examined and one infected, 50 per cent.; Durham Co., two men examined and one infected, 50 per cent.; Roberson Co., five men examined and three infected, 60 per cent.

South Carolina.—This State furnished six of the above fifty-three cases, distributed as follows: Florence Co., six men in school, four were examined, all infected. Two would not submit stools, but in appearance were as typical as other cases from same county. Another case came from Marion. In the last case I did not get the county. One of the above fifty-three cases came from Sevier Co., Tennessee, a very mountainous county. These are facts, and are not hard to interpret. That there could have been no mistake in recognizing the eggs I will state that in 70 of the above 147 cases, where I have heard from the effect of treatment, in not a single case, did thymol fail to show the worms in the stool. Its occurrence in Iredell, Burke, Wilks counties, North Carolina, and in Sevier Co., Tennessee, would indicate that the clay counties are by no means immune. According to our observation, the cases are not as frequent, and not as severe as they are from Eastern Carolina. Add to these fifty-three students, seventy-one cases occurring in the practice of Dr. Nicholson, of Richlands, Onslow Co.; four cases for Dr. E. L. Cox, of Jacksonville, Onslow Co.; six cases for Dr. S. N. Harrell, of Tarboro, Edgecombe Co.; four cases for Dr. I. F. Hicks, of Dunn, Harriet Co.; one case for Dr. H. W. Lewis, of Jackson, Northampton Co.; one case for Dr. R. H. Speight of Wrendale, Edgecombe Co.; seven cases for Prof. Stevens, which he had collected from the State's prison, and we have 147 cases. From the 147 cases, etiological records have been obtained from 118 cases.

These records bear especially upon the relation of dirt eating, drinking water and ground itch to the disease.

Etiology.—This part of our subject naturally divides itself into two heads: First, a study of the anatomical and biological characteristics of the parasite, and secondly, its mode of entrance into the host. About the first we know much, about the second, little. And it is this very part of the etiology that concerns us most, for upon this knowledge will depend the rational and effective application of preventive measures. I shall consider the anatomy and biological characters first.

Anatomy of the Worm.—Dubini, of Milan, Italy, discovered the cause of the European type of the disease in 1843 and called it *Anchylostoma duodenale*, or *Uncinaria duodenalis*. In 1902, Dr. Charles Wardell Stiles, comparing worms collected from different countries noticed a difference in the American and European worms, thereby discovering a new species as a cause of the American form of the disease. This worm he has named *Uncinaria Americana*. This is a nematoid worm, a member of the family *Strongyloidæ*, whose members are characterized by the following points: Body cylindrical, rarely filiform; mouth in axis of body, dorsally or ventrally flexed, and surmounted by six cubical papillæ, four of which are submedian. Esophagus, more or less swollen posteriorly. Male presents a caudal bursa which may be complete or divided, and encloses one or two spicules. Female presents a vulva anterior or posterior to midline and two ovaries. This family is divided into two subfamilies and it is to the subfamily (*Strongylinæ*), the genus *Uncinaria* belongs. These are worms whose mouths are surrounded by a chitinous armature. Male presents a caudal bursa, with lateral and dorsolateral rays arising from a common base. Female presents two ovaries. Of the genera which compose the family, *Strongylinæ*, the genus *Uncinaria* is characterized by the dorsal flexure of its head, giving it a hook-like contour, from which it derives its name. Let us study the anatomy a little closer: Male, 6 to 9

mm. long; female, 8 to 11 mm. long; both about 4 mm. in thickness; color, white, or occasionally brown from contained blood; shape, head of male dorsally flexed, giving a hook-like contour, tail of male expanded, umbrella-like, tail of female conical.

Now to start at the head, we have a cup-like arrangement, measuring 100 μ anteroposteriorly, transversely and in depth. This cup is composed of four pieces, two curved quadrilateral plates incompletely united, ventrally and dorsally. Dorsally this incomplete union is strengthened by a dorsal reflection of the dorsomedium tooth, making the third of the four pieces, and the fourth piece exist in the form of a rim to the cup. This rim gives off on each side two lips, the two ventral are symmetrical semilunar-shaped and project well into the oral cavity. The two dorsal are rudimentary and only reach oval margin. Beneath these lips are six papillæ, three on each side, two beneath the ventral and one beneath the dorsal lip. The oral mucosa is reflected in folds to these papillæ, giving to the pharynx, when viewed from above downward a striated appearance. At the bottom of this cup begins the mouth proper. This is elliptical in shape and measures 50 to 70 μ anteroposteriorly and 40 to 50 μ transversely, but this shape is variable, as it is subject to muscular movements. Surrounding the margin of the mouth is a delicate transparent cuticle, continuous with the oval mucosa. Projecting into the base of the mouth is the esophagus with an armament worthy of description. This consists of a large tooth placed in a dorsomedian line, convex on its outward surface and concave on its inner surface. On each side of this dorsomedian tooth we have two sharp chitinous pointed lancets. The pair closest to the tooth are very sharp, point transversely and are known as the lateral lancets. The two more ventrically placed are more conical in shape, look backward and are known as the ventral lancets. These five structures are connected by a fold of oval mucous membrane so arranged as to leave a crescentic opening to the esophagus.

The esophagus is bottle-shaped, the large end posterior, measuring 750 μ in length by 160 μ in its thickest portion. It is composed for the most part of a thick muscular wall. Cut transversely, its opening appears triradiate posteriorly as it opens into the intestine, this opening is guarded by a valve. Lying along the esophagus are two glands, whose secretion is emptied just within the line of the ventral lancets. It is supposed that this secretion prevents the coagulation of the blood sucked out by the worm and is also supposed when absorbed by the host to exert a toxic effect. Now notice this effective blood-sucking arrangement. The muscular esophagus forces its pharyngeal portion into the chitinous cup, and the lancets and tooth now lie against the cup's walls. The esophagus retracts and more or less of a vacuum forms, the rim of the cup having previously been placed against the intestinal mucosa. Into this vacuum, the cup, this intestinal mucosa bulges in the form of a little pledget, which the large hook-like dorsal tooth catches in its return to its position and holds, while the lateral and ventral lancets play back and forth, continually wounding the delicate mucous membrane. This blood is kept fluid by the secretion of the two large glands above mentioned, sucked into the strong muscular esophagus, and emptied into the intestines. A return into the esophagus is prevented by a valve which guards its opening into the intestines.

Here we have an arrangement very much like a Davidson syringe. The intestine empties on the ventral surface of the female close to the tip of the tail. In the male it empties in common with the genital aperature, on the dorsal side of the conical papillæ within the caudal bursa. The worm is covered with a delicate transparent cuticle, laterally striated and this shows dorsal, ventral and lateral longitudinal markings. Beneath the skin is an encircling layer of muscularis with inward extensions for the support of the esophagus, intestines and genital organs. The generative organs in the male consist of two plicated tubular testicles lying along the intestine. These empty about the middle of the worm into a seminal sac, and this again empties by a duct on the dorsal side of the caudal nodule, through which passes a forked, barb-tipped penis about 9 mm. in length. The female generative organs consist of a vulva, placed anterior to the midline of the worm, and this is composed of two transverse folds. This vulva leads into a short vagina, which terminates in two uteri. These are tubular, one coursing posteriorly, the other anteriorly. The uteri terminate in two tubular ovaries, both of which coursing anteriorly, lie in plicated folds along the intestine.

The caudal bursa is so important in the differentiation of species, that it demands rather detail description. It is composed of an excess of cuticle, forming an umbrella-like expansion and this umbrella is held open by finger-like prolongation of the encircling muscular cord backward. These supporting muscular prolongations are called the caudal rays. The bursa is divided into two well-marked lateral lobes, a divided dorsal lobe and rudimentary ventral lobe. The dorsal ray arises by a common base with the dorsolateral ray, the dorsal ray going to the dorsal lobe, where it ends bipartite, the dorsolateral curving downward into the lateral lobe. The ventral ray is also bipartite and just within in its base we find a rudimentary subventral ray. The male uses this bursa in clasping the female *in coitu*. The thousands of eggs, deposited in the stools furnish the doctor with a diagnostic omen and the ignorant laity with a source of infection.

The description of the eggs is most important. They are oval, symmetrical in shape, measuring

68 by 38 μ in size, composed of a beautiful laminated transparent shell, enclosing a granular or segmented yolk. We never find the eggs enclosing an embryo in the fresh stool. The egg must develop outside of the body, and therefore, for every worm in the intestine the host must have swallowed a young uncinaria. These eggs, when exposed to a temperature of from 21° to 37° C., and kept in a semisolid stool, supplied with oxygen, hatch out into the rhabditiform embryo in about forty-eight hours. This hatching is delayed by too much moisture, lack of oxygen, or being kept in the dark. Drying destroys the eggs in twelve hours. In about three days after hatching the young worm reaches the second ecdysis. This worm lives well in water. This is the infective stage. After entering the host, it passes through other stages, until it finally develops into the mature parasite.

Let us now return to its mode of entrance into the host. This is important, for the preventive treatment depends upon a correct understanding of this point. Three possible routes of infection exist: (1) Taking the food contaminated with fecal matter, in other words dirt-eating; (2) through the drinking water; (3) through the skin in the lesions of ground itch. Let us study these portals of entrance a little more in detail.

The first, dirt-eating, we can readily understand. It is the simplest. Dr. Stiles seems to think it is the principal mode of infection. So much importance is attached to this view, the disease is known as dirt-eater's anemia, brickmaker's anemia, tunnel anemia, miner's anemia, etc., all occupations associated with soiled hands, and of course a certain amount of dirt-eating. Then we must not forget that dirt may get into the mouth on fresh vegetables, grown in the ground, such as water cress, celery, radishes, etc. Here it is necessary to keep in mind Allen J. Smith's caution, that all dirt-eaters are not predisposed to hookworm, for some dirt could not possible harbor the larvæ, such dirt as soot, ashes, brick and mortar. Again we should remember that dirt eating is often an effect and not a cause of anemia. Every clinician knows about the "longings" of pregnancy and anemic conditions for such things as clay, sand, etc.

Second Mode of Infection, Drinking Water.—As Dr. Stiles has pointed out and I have frequently verified, the eggs die or degenerate rapidly in water. So that if a stool was washed immediately after voiding into water, the eggs would rapidly perish. Not so if the stool is deposited on the ground for two or three days, until the eggs hatch out into the second stage. Now if a rain falls, the parasites are carried into a nearby stream, spring or surface well.

Loose has shown that these worms pass rapidly through sand filters, and that they will live thirty days in water. These larvæ, once in the water, sink to the bottom of the well; but the bucket also sinks, and could as easily bring up the young larvæ, as it does the grains of sand contained in nearly every bucket of water. Dr. Smith seems to think the wind plays a part in spreading the dry feces in the form of dust on the house tops, where the eggs can easily be washed down by the first rain into the cistern, and there develop; but experimental evidence proves that both the eggs and larvæ die rapidly on drying. So until it is proven, that the eggs can withstand drying, we can disregard the wind as a factor in spreading the disease.

Third, ground-itch, as a portal of entrance: we have purposely left this until the last, because we want to go more in detail here, as we believe it the principal portal of entrance in Eastern Carolina. What relation does ground-itch bear to uncinariasis? That is, we think, an important question to answer. Now, in considering this phase of our subject, the first question to present itself is this: Is ground-itch infectious? Here is the evidence derived from the articles of Elliott (?), of Assam, India, who gives clinical evidence, from Dalgetty, South Silhet, India, who furnishes clinical and experimental evidence, and, lastly, from Bentley, in South Africa, who gives experimental evidence, and all this answers the question in the affirmative.

In *The Journal of Tropical Medicine* for December, 1900, Elliott reports the clinical features of ground-itch, and in considering the cause arrives at the following conclusions: (1) The disease manifests itself from May until September, the largest number of cases occurring during the months of July, August and September; (2) It occurs after heavy rains, when the ground is moist and sticky; (3) it occurs only in those who go barefooted and expose themselves to the wet earth; (4) it does not occur at all, or only slightly, on new land; (5) cases are most numerous and severe in those who work about the lines where the ground is thoroughly manured. The frequency and severity of the cases seem to bear a close relation to the fecal content of the soil.

Then to produce ground-itch, we must have contact of the bare skin with fecal-contaminated soil, at a certain temperature and containing a certain amount of moisture. All of these five factors must be present, *i.e.*, (1) bare skin, (2) soil, (3) feces, (4) moisture, and (5) certain temperature. The first three of these conditions will not produce it. Ground with proper temperature, fecal contamination and bare skin will not produce it, else it would occur in April and May, when the ground is dry. Ground with requisite moisture and temperature does not cause it; if it did, it would not be so rare on new lands. It is not airborn or the Europeans would suffer alike with the natives. The Europeans wear shoes. We have here a mass of circumstantial evidence that points, first, to infection as a cause of ground-itch, and second, the infectious agent as derived from the human feces.

Assuming infection, what is the infectious agent? Do you notice any conformity of above conditions, *i.e.*, feces, temperature, moisture, etc.,

to the biological requirements of the hookworm? You certainly do.

Is it possible that these parasites produce ground-itch? Allow Bentley to answer: Having had his attention attracted to this possibility, by finding a rhabditiform in the lesions of the ground-itch, he performed the following experiments: He took two stools, one we will call "A" and the other "B." "A" was infected with the larval uncinaria. "B" was free from uncinaria. He then sterilized a mass of sand. Dividing this, he mixed part with stool "A" and part with stool "B." Now "A" was divided into two portions which we will call "a′" and "a″." "B" was likewise divided into "b′" and "b″." "a″" and "b″" were now exposed to the air for eight hours till dry. At this time all four portions were applied to the bare skin. "a′" produced an erythema exactly resembling that of ground-itch and on examining "a′" most of the worms had disappeared, only a few dead larvæ remaining. "a″" contained the original number of dead embryos. Of course these were killed by the eight hours' drying.

Dalgetty agrees with Elliott on the predisposing causes, viz., temperature, moisture, feces, etc., but differs with Bentley as to the exact cause. Dalgetty's work preceded Bentley's by two years. Dalgetty attributes ground-itch to the *Rhizoglyphus parasiticus,* a parasite closely resembling the itch mite; and its association with fecal material, he explains by saying that the parasite lives best on rich organic matter. We are not inclined to accept Dalgetty's theory as to the direct cause for these reasons: First, from his paper, his technic appears faulty. Second, he does not give the per cent. of cases, in which this parasite was present, a condition concerning which he would not have remained silent had he found any number of cases. Third, it fails to explain the association of ground-itch with fecal contamination of soil. It therefore seems very probable that ground-itch, as claimed by Bentley is an infectious dermatitis, due to the entrance of the larval *Uncinaria,* carrying in with them certain bacteria, which modify the lesions.

Assuming that ground-itch is due to infection with these larvæ, we may very properly ask: Does this cutaneous lesion bear any relation to the intestinal lesion? To answer this, we refer you first to Loose's experiments. Loose is a careful man, and his work is accepted by all authorities. His experiments were done as early as 1898. He examined the feces of two puppies, and assured himself that they were not infected with hookworms. He then shaved their backs, and applied to their bare skin a poultice composed of infected stools and charcoal. Both pup pies died on the ninth day after the poultice was applied, and many young hookworms were found in their intestines, which corresponded in stage of development to young worms in another dog's intestine, which dog had been infected from the same stool from which the poultices were made. Then he performed the same experiment on a man. His stools were examined and found free from hookworm eggs. Then a poultice composed of feces with hookworm larvæ in them was applied to the back of the forearm. On the seventy-first day thereafter, the man showed hookworm eggs in his stools. This proof that uncinaria may enter through the skin, is accepted. It is not without analogy.

The weight of evidence goes to prove that this occurs in infection with the *Bilharzia hematobia,* where the parasites are found in the ureter, bladder and kidneys. But, you say, having entered, how do they locate in the intestine? We do not know how, but we know they do.

The selective affinity of various parasites for different tissues, is a well-recognized fact, and is accepted by all authorities. We have example of this selection an infection of the brain with *Cœnurus,* infection of the liver with *Ecchinococcus* or *Amœbæ,* infection of the muscles with *Trichinæ spiralis,* and lately an infection of the intestine with *Anchylostoma duodenale.*

The fact stands, and some day the explanation will follow. Now, assuming that the frequency is accepted, we believe you will all agree that the preventive treatment is the most important, for upon this will depend the extermination of the disease.

To effectually and rationally apply the prevention it is necessary to know the route of infection.

Of the above three routes of infection, *i.e.,* dirt-eating, drinking water and ground-itch, we think we can safely accept all as possible routes, and in applying our "ounce of preservation," all must receive due consideration. But which is the most important route? Which portal is the most accessible to the hookworm? To answer this question we have collected etiological records from 118 cases distributed as follows:

71 cases from Dr. J. L. Nicholson's practice, Richards, Onslow Co.
3 cases from Dr. Cox's practice, Jacksonville, Onslow Co.
4 cases from Dr. Hicks' practice, Dunn, Harriet Co.
4 cases from Dr. Harrell's practice, Tarboro, Edgecombe Co., and
35 cases from Wake Forest students.

Race.—All of the 118 cases were white. We could not find a single case in the negro, although Dr. Nicholson's practice is in a country, where about one-half the population are negroes. Considerable trouble was taken to find it in the negro. Only one negro was encountered who presented suspicious symptoms. Microscopical and thymol test were both negative. Some have held that this relative immunity of the negroes was only apparent and not real, that the prominent symptom of uncinariasis, pallor, was absent on account of the negro's color. This is a mistake, for not only is the pallor absent, but the other symptoms of uncinariasis as well. It is there-

fore our experience that the negro is partially immune. He is, however, as susceptible to ground-itch as the white.

Sex.—Of course the students were all males and in considering the influence of sex should not be taken into count. Of the other 82 cases, 47 were males and 35 females.

Residence.—Of the 118 cases, 109 lived in the country, nine in town, but this includes 71 cases from Dr. Nicholson's practice, all of which were from the country. It is not right to consider these in the etiological bearing of residence. We shall therefore only consider the bearing of the 35 students on this point. All of these students except seven were from the country. These seven, with the exception of two, were from mere villages, and all 35 had lived in the country at some period of life.

Soil.—It is most frequent on a soil composed of an upper layer of fine, gray, compact sand, with a substrata of clay about six or ten inches below the surface. Another soil that seems favorable is the loamy, fine, sandy soil, *i.e.*, a fine sand mixed with much decaying vegetable matter. Here we may have no clay subsoil. It has been interesting to observe its almost entire absence on a soil made up of coarse sand, six or eight feet deep. We account for this distribution on the biological requirements of the parasite. On the first two of the above soils, you have a structure to hold moisture, on the last, rapid drying and death of the parasite.

Occupation.—117 worked on farms, one worked in a cotton mill, but had lived on a farm.

Age.—The youngest patient, two years and four months old; the oldest patient, fifty-six years; two were fifty years old. The students ranged from seventeen to thirty years, 12 were under and 18 between twenty and twenty-five years, making 30 of the 36 patients under twenty-five years of age.

Under five years there were	5 cases
Between fifth and tenth year	14 cases
Between tenth and fifteenth year	28 cases
Between fifteenth and twentieth year	15 cases
Between twentieth and twenty-fifth year	9 cases
Between twenty-fifth and thirtieth year	2 cases
Between thirtieth and thirty-fifth year	4 cases
Between thirty-fifth and fortieth year	1 case
Between fortieth and forty-fifth year	0
Between forty-fifth and fiftieth year	3 cases
Between fiftieth and fifty-fifth year	0
Between fifty-fifth and sixtieth year	1 case

Average age of onset seven and one-half years.

Under ten years of age, 70 per cent of our cases were infected.

Family Disease.—Of 70 cases in Dr. Nicholson's practice, 39 families were represented. These families number a total membership of 280. Of the 280, 32 per cent. have been microscopically diagnosed, and 25 of the remainder clinically diagnosed uncinariasis. Again it has been noted that it seems to be a family trouble generation after generation. Furthermore the large number of aggravated cases, seen in certain families, would seem to indicate that prolonged and intimate association upon a soil intensely contaminated an etiological factor of great importance.

Dirt-Eating.—Of the 36 students, three admitted dirt-eating, two ate parched coffee, and 31 denied dirt-eating. Of the 82 mixed cases, 64 denied dirt-eating, eight confessed, five chewed rosin, two chewed rags, two chewed sticks and two chewed coffee. A close study of our cases does not encourage us to attach much importance to dirt-eating as a source of infection. And by dirt-eating, we mean putting anything in the mouth contaminated with feces, either the soiled hands, fresh vegetables, as celery, water cress, etc., or the soil itself.

Drinking Water.—All of our cases show a questionable water supply. Those from Eastern Carolina, drank from surface wells, varying from six to 25 feet in depth. Many of these wells were uncurbed and uncovered. Our Western cases from the mountainous country drank from springs. And as it is a custom on farms, both western and eastern cases occasionally drank from creeks, while out at work. Notwithstanding this questionable water supply and Loose's demonstration, that the larvæ pass rapidly through sand filters, and live well in water for at least thirty days, we are not inclined from a study of our cases to attach much importance to drinking water, as a source of infection. Like dirt-eating, we believe it a probable source, and possibly accounts for the scattered cases or the light cases, and those which develop without a preceding attack of ground-itch. Our reasons for this view are, (1) If it is due to drinking water why should children be more often infected than adults? They drink less water, and therefore would not be so much exposed to contagion as the adult. Our statistics show that 70 per cent. of the cases begin before the tenth year. (2) If it is true, as has been suggested by some authorities, that it is due to the careless drinking of water from springs and creeks, then it should occur principally in males, and be more frequent after the fifteenth year, for it is not until this age that the child begins to work away from the house on the farm. (3) Again, here is a careful observation that opposes the water theory of infection. The tenant classes usually move every year or two to a new farm; they usually move in the winter. The ground is sterilized by the frost and snow. A new tenant moves in, and if the well is the source of infection, you would suspect the new family to become victims. This does not usually follow unless the new family have the same unclean habits as their predecessors.

Ground-Itch.—Every case, except one, gave history of ground-itch. This exception was a case from Iredell Co., who said he did not know what ground-itch was. Admitted that he had suffered with dew-crack. Now the above etiological data when considered together would seem to justify the conclusions, *that the mass of*

evidence favors ground-itch as the most important factor in the transmission of the hookworm disease, and that while drinking water and dirt-eating are predisposing factors, they are not so important as ground-itch.

What are the grounds for such a conclusion?

1. It has been noted that in localities where ground-itch is frequent, there hookworm disease is also frequent. Where there is no ground-itch, there is little or no hookworm disease.

2. Then over 99.5 per cent. of 150 cases gave a history of ground-itch. If we accept Bentley's theory of ground-itch, *i.e.*, a dermatitis due to the carrying in of bacteria by the entrance of hookworm larvæ, and not to the larvæ themselves, we can then explain those cases without ground-itch as due to larvæ entering with only a few bacteria or non-virulent bacteria. In other words, the question is whether these larvæ can enter without producing a local lesion, as suggested. Probably a better explanation of the cases without ground-itch, is that they were infected though water or dirt-eating.

3. In 69 out of 90 cases, the history was that ground-itch preceded the development of the other symptoms. In 18 cases, the patients could not be sure about this point.

4. We have noticed that in the majority of cases, the severity and number of attacks of ground-itch bear a definite relation to the severity of uncinariasis. Severest cases give a history of severest ground-itch.

5. The age of our patients affords valuable information. A glance at the age table impresses one at once, that the disease is definitely associated with the period of life when the child goes barefooted. It does not occur, except rarely, under three years of age, for until then the child runs about but little, and then indoors, and it is not allowed to run about after rains until the ground is dry. From this age, one will observe a definite and steady increase until the fifteenth year, when there is a decline. This corresponds to the period of greatest activity of barefooted children. In the South, these children begin to wear shoes all the year round at the ages of thirteen to fifteen years. Cases are comparatively uncommon beyond the twenty-fifth year; rare beyond thirty, and when they do occur, are light and nearly always on the decline. Among the students, the disease was light and on the decline. This was because these men had been wearing shoes the year round for the last five to ten years. Here is an interesting observation, bearing on the association of barefootedness with uncinariasis. Of my 53 students, 36 were treated with thymol and the number accurately counted after the method of Allen J. Smith in the November, 1903, number of *The American Journal of the Medical Sciences.*

The average number of worms passed was 20 in 35 of the cases. These men had ceased to go bare-footed at the age of twelve to fourteen years. There were six men from Sampson Co., who went barefooted in the summer until seventeen to twenty-four years, this being a peculiarity of these men. They were given the same treatment as the others, but passed an average of 113 worms. The number passed by these six men were 350, 120, 100, 68, 32 and 10. In our cases we have frequently noticed this association. Our severe cases, beyond twenty years of age, are in those who have gone barefooted much of their lives.

6. As pointed out above, it is a family disease. Occasionally we have single cases in a large family. This case for instance; a child twelve years old, a member of a family of eight children, was the only one affected. An intelligent mother affirms that she is the only child who ever suffered with ground-itch.

7. We have observed, what may be termed acute uncinariasis. To illustrate we give as an example, G. S. N., aged nine years, male. Healthy all his life. September, 1903, a very severe attack of ground-itch, could not walk and had to remain from school. This attack lasted one month. Latter part of October and early November began to show anemia, poor appetite, listless, headache and diarrhea. These symptoms continued, increasing in severity until December; he presented on inspection a picture of chronic parenchymatous nephritis. Stools were examined microscopically. Many *Uncinaria* eggs were present. Thymol was used, a large number of worms were expelled, the anemia treated, and complete recovery followed.

We have four more similar cases, where there is one severe attack; it may be the only one ever suffered from, and this is followed in from six to eight weeks by rapid and profound anemia, which yields promptly to thymol and iron.

8. When the patient ceases to be troubled with ground-itch, it is the rule for improvement to begin. Age table shows this.

9. Allow us to offer one more point in favor of ground-itch as a cause, at the same time reporting the youngest case on record.

A baby, two years four months old, a member of a family of six children. The mother and the other five children have been microscopically diagnosed uncinariasis. This family lives in a log cabin on a *dirt floor.* In the summer, when this child was seventeen months old, the mother and the other children assisted a neighbor to "hang tobacco" a little way from her cabin. The baby was left at home on the dirt floor. In a very short time the baby suffered with three attacks, of what the mother calls "mad-itch," over the buttocks and posterior thighs. Up to this time the baby was red-faced and healthy. Now there started a decline, so that when this case was seen, last month, it was one of the most distressing and well-marked cases of uncinariasis that has come to our notice.

In conclusion, allow us to ask this question: If drinking water and dirt-eating are responsible for the majority of cases, as Dr. Smith and Dr.

Stiles would seem to favor, why does it occur so rarely under three years of age? For who gets more dirt than the baby, and why should it harbor other intestinal worms more frequently than any one else, yet fail to show hookworms? And if drinking water is such a causative factor, why should it be more frequent in children, who drink less water than adults?

We therefore conclude, *concerning the etiology of hookworm disease, that ground-itch is by far the most important portal of infection, and that dirt-eating and contaminated water supply, while capable of infecting, are not nearly so important as ground-itch as a source of infection.*

A CASE OF PNEUMOMELANOSIS.

BY FRANK I. GIVEN, M.D.,
OF HILLSBORO, NEW MEXICO.

John Ryan, age fifty years, of Irish descent, occupation gold and copper miner. Began to lose strength and flesh and develop cough about 1898. Did not become incapacitated for the purusit of his vocation until about 1900. Had been a hard drinker for years.

Physical Examination, January 8, 1904.—The chest seemed abnormally large, measuring 48 inches at the fourth rib. Expansion one-half inch. Percussion note flatter than normal over the entire pulmonary area, excepting at the apices where it became slightly tympanitic. Moist bronchial râles over the trachea and bronchi. Bronchovesicular respiration over the lower lobes, the vesicular quality gradually diminishing toward the apices where the sound became blowing in character. Vocal resonance and fremitus were negative as far as any aid to diagnosis was concerned.

The heart's action was feeble, but there was no indication of organic trouble. Abdominal organs were normal. There was present a comparatively scanty expectoration of a jet black sputum about the consistency of that of ordinary phthisis. At times there was present in the sputum particles of calcareous material varying in size from that of a grain of rice to fine grit. Death occurred January 13, 1904.

Autopsy Eight Hours Later.—Body very much emaciated. Skin dry and scaley. Several hemorrhagic petechiæ on the extremities but none elsewhere.

Heart.—Atrophied. Heart muscle very friable. About one ounce of liquid in the pericardium.

Lungs.—Both about one-fourth larger than usual. More firm at the touch than normal. Mottled black and pink in appearance, black predominating. Numerous extensive and strong adhesions at the apices. So strong were these adhesions that both apices were torn off on removal. The upper three fourths of both upper lobes were jet black in color, externally as well as on section. Cavities were present in both apices, irregular in outline, that in the left apex being the larger. Projecting into the cavities were numerous calcareous bodies. Cutting through the upper lobes was like cutting through a bag of gravel. The cavities and bronchial tubes leading from them were filled with a jet black sticky material resembling the sputum during life. The lower lobes were mottled in appearance both externally and on section, resembling in appearance a section of sausage, only the colors were black and pink, the black largely predominating. Several grayish puckered areas were noted on the surface of the lungs resembling cicatrices. These places on section were invariably found to contain calcareous material jet black in color. The mediastina contained many enlarged hard (like cartilage) jet black lymph glands. There were about two ounces of liquid in the pleural cavities.

Liver.—The right lobe was slightly enlarged. No pigmentation either externally or on section. A few small black glands were noted in the folds of the peritoneum beneath the liver.

Spleen.—Slightly enlarged, but in not sense melanotic.

Stomach.—Atrophied; mucous membrane covered with mucopurulent secretion. Several hard black lymph-glands were seen along both the upper and lower borders of the stomach.

Pancreas.—Normal.

Kidneys.—Right, normal; left, movable over a radius of our inches; otherwise normal.

No black lymph glands were discovered below the region of the stomach.

Brain and osteomyelon not examined

Diagnosis.—Pneumomelanosis with tuberculosis complication.

MEDICAL PROGRESS.

MEDICINE.

Theory of Alkaptonuria.—An important observation made in that peculiar chemical malformation known as alkaptonuria, is that homogentisic acid when given by mouth is excreted as such, while the normal organism can still further decompose it. In the experiments of W. Falta (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 3 and 4), almost the entire quantity ingested could be recovered from the urine. The only other instance in which the acid could be detected in the urine was in a severe case of diabetes with absolute intolerance toward carbohydrates, for soon after the patient had taken four grams of homogentisic acid the brown color of his urine was very noticeable. In plants, tyrosin and phenylalanin are decomposed with the intermediary formation of hemogentisic acid, and the same process probably goes on in every normal animal body. With alkaptonuria, however, there is an inability on the part of the system to break up the benzol ring of the acid into simpler principles (urea, carbon dioxide and water). Little is known as to how the tyrosin and phenylalanin molecules of albumin are absorbed under normal conditions, but it seems probable that most of the tyrosin is split off in the intestines and absorbed as such while phenylalanin is absorbed as constituent of a more complex molecule. It is certain, however, that homogentisic acid is formed very soon from both. The metabolic

activity of the alkaptonuric is not abnormal with reference to the breaking down of the other constituents of the proteid molecule, and it is possible for him to remain in perfect health, despite his abnormality.

Changes in Nails in Scarlet.—Attention is directed to a new postscarlatinal symptom by E. Feer (*Münch. med. Woch.*, October 4, 1904). Four to five weeks after the onset of scarlet, at a time when desquamation is nearly completed, a transverse furrow or a distinct elevation will appear upon the root of the nails of the fingers, particularly the thumbs. As the nail grows, this furrow will advance, until at the end of five or six months it has reached the free surface. The prominence of the line is generally in direct proportion to the intensity of the eruption, and in very young children there may be difficulty in finding it. In a small percentage of cases of measles a less prominent line may also be detected, but not in other diseases. By the position of the line, it may be possible to state at what time the patient suffered from his scarlet and the scarlatinal origin of a nephritis or a rheumatism may thus be settled.

Insanity and Epilepsy in Relation to Life Insurance.—It will not be long before the great insurance companies are in possession of more reliable data bearing on the relation of certain diseases for the shortening of life than are to be found elsewhere in the archives of the medical profession. W. R. Gowers (*Lancet*, October 15, 1904), in an address delivered before the Association of Life Assurance medical officers, October 5, 1904, basing his remarks in part upon the medical experience of Dr. Claude Muirhead, from 1874 to 1894, in his experience with the Scottish Widows' Fund, in part upon his own personal observations, he said that the first practical question to be asked in the matter was whether or not any actually insane person should be considered a justifiable risk under any conditions. He believes that the answer to this is a qualified "yes." Obviously no one suffering from acute mania or melancholia can rightly be looked upon as insurable. The pitfall of making sweeping conclusions from single isolated cases had been avoided too conscientiously. Such cases have occasionally a very marked value, and he cited one in which the company made the largest relative profit of any case that it had done under the author's observation. A man, twenty-eight years of age, was insured in 1830, after he had been a resident of an asylum for twelve years. He died sixty years later, the diagnosis in the case being imbecility in consequence of epilepsy in early life. The profits on this case were $230,000 for the insurance company. Chronic imbecility, if not attended with deterioration of the vital organs, is not to be rated among afflictions which shorten life. Of the two types of idiots, the congenital and acquired, of which latter form this man was an example, Gowers believes that the acquired form is by far the better risk. Certain cases of paranoia, in which the delusions had become fixed, not only in type but in extent, are also good risks. Suicide is a factor with which insurance companies have to deal widely. It is apt to be much higher in the insane than in the sane. In Dr. Muirhead's 9,000 deaths, 127 were due to suicide. Insane heredity, curiously enough, does not seem to have any greater bearing upon suicidal probability than an ordinary neurotic family history. The conclusion of the author in regard to the bearing of family history insanity on a given risk, whose physical and mental condition at the time of examination is good, should not count for anything. The average age of 40 epileptics on entry was thirty-two years, and at exit by death forty-eight years. In only one case was there any hereditary history worth paying any attention to. Many of the cases insured by this fund probably suffered from so-called nocturnal epilepsy. Probably the chances after twenty years of age that a child of epileptic parentage will suffer from the disease are about one in fifty. When to this small ratio is added the fact that epilepsy tends to shorten life in but small degree it does not seem that family history should be entitled to any consideration whatsoever. It is different, however, with individuals in whom the disease has actually developed. Are they insurable? Frequent attacks of epilepsy should probably bar the case absolutely from insurability. Occasional attacks, however, in patients who have passed middle life, may, in chosen cases, be regarded as not constituting insuperable objections.

True or Inoculated Rabies.—Under this title a case is reported by L. Heydenreich (*Berl. klin. Woch.*, September 19, 1904) in which a doubt existed as to whether the symptoms were due to the bite of the rabid dog or to the preventive inoculations. A woman, aged forty-five years, was bitten by a young dog, which was almost immediately killed without having given any evidences of having had rabies. The patient was given Pasteur treatment, 24 injections being made within twelve days, beginning five days after the injury. On the eighth day of treatment, a series of symptoms came on, regarding which it was doubtful whether they were due to true rabies or the inoculated modified form,—malaise, nausea, slight cerebral disturbance and stupor. These increased in severity and were accompanied by obstinate constipation, paralysis of the bladder, dyspnea, mental depression, with paresis of the face, tongue and pharynx. Gradual improvement came on after a month, but then she became melancholic and finally a complete idiot, dying within ten months after the injury. It seems probable that in this case the symptoms were due to the inoculations, for the disease began to show itself within thirteen days after the bite, which is unusually early, particularly as the injury was very superficial. Another servant in the same house was more severely bitten by the same dog, but was not treated and remained perfectly well. The dog in all probability was not mad. The case is of interest because the symptoms could be traced without much question to the inoculations, and the production of such a modified form of the disease has usually been ascribed by other authors who have observed it to the character of the bite itself. The author thinks that if the treatment had been continued, so that a true immuniy was developed, the woman might have been saved.

SURGERY.

Treatment of Ununited Fracture of Neck of Femur.—It is not at all uncommon to encounter patients, either in full activity or only slightly past adult life, upon whom the most exacting limitations have been placed by this sequel of fracture. Leonard Freeman (*Annals of Surgery*, October, 1904) states that it is extraordinary, in view of the excellent results obtainable from the open operation, that so few cases are to be found recorded in the literature of the subject. It may be that one reason for the limitations on the operation is that most of the patients are very elderly, and are obviously unfit for surgical intervention. The technic of the operation centers chiefly on two points, viz., the position of the incision and the method of uniting the fragments. There can be little doubt that the anterior incision is to be much preferred to the posterior. It

should begin just below and external to the anterior superior iliac spine. It will thus lie between the sartorius and the fascia lata. The removal of the soft parts interposing between the fragments must be thorough. By the time the patient is operated on, this tissue has usually become well organized and may be highly vascular. The fixation of the fragment is the most difficult problem. One of the most important points in accomplishing this lies in securing the support of the trochanter from behind. While extension, combined with this support, will, in many cases, give excellent results, it is probably safer not to trust to these alone. Nails, screws or bone or ivory pegs may be inserted obliquely either through the original incision or through a small opening over the trochanter. These appliances, however, because of the extreme porosity of the bone, often do not hold it in place at all adequately. For this reason Parkhill suggested the use of his bone clamp. The author has devised a clamp, the efficiency of which lies in the fact that the screws bury themselves as firmly as if screwed directly into the bone. The question when to remove the supports is a difficult one. If infection occur, they should be taken out at once. In the author's own case, there was evidence of sepsis at the end of two weeks, but perfect drainage and subsidence of symptoms resulted from a removal of the screws. The majority of operators have placed the time for staying in bed at ten weeks. This is probably the minimum, because of the well-known osteoporosis, which almost invariably affects the region of the femur in these sequels of tracture of the neck.

Meckel's Diverticulum.—This interesting but inconstant remnant occurs not infrequently within the sac of external herniæ. Frank E. Bunts (*Annals of Surgery*, October, 1904) states that although the credit must be given to Johann Friederich Meckel for having called general attention to the organ, as well as for his well-known classical essay describing it, Lavater is said to have been the first to have recorded observations upon it. Ruysh in 1701 called attention to this abnormal development, which he described and illustrated in his "Thesorus Anatomicus." Morgagni in his "Seats and Causes of Disease," reports several cases of Meckel's diverticulum. It was Meckel, however, who advanced the theory that it represented the remains of the omphalomesenteric duct. While this origin of the diverticulum is generally believed, there are those who consider that it arises from the vitello-intestinal duct, and claim that it is developed as the result of traction upon the intestines by the omphalomesenteric duct. Disconnection between the duct and the gut should take place at about the third month. Rolleston has found it in 3 57-100 per cent., Osler in 2 per cent. Mitchell found it in 39 cases out of 1,635 patients examined. It is considerably more frequent in the male, only four women having occurred in Mitchell's 39 cases. It is usually present in the lower fourth of the ileum. It does not appear, however, that it is restricted with any great degree of positiveness to any particular portion of the alimentary tract, for it may be located anywhere between the esophagus and the ileocecal valve. This variation in position is explained on developmental lines. The loop from which the lower part of the duodenum, the cecum and colon are developed, is usually U-shaped. At the point of greatest convexity the duct is attached. The great length of the small gut, which subsequently develops from the upper limb of this flexure, usually places the duct in a position near the valve. Very slight variation, however, in point of attachment of the duct to the loop will at term place the duct in very widely varying positions. The length of the duct varies from a small blunt projection to a diverticulum ten inches in length. It is usually tubular, resembling the finger of a glove. The diameter is often nearly equal to that of the gut itself. Indeed Stillman states that it may exceed it. The author reports the history of a male who, presenting exidences of an ordinary strangulated inguinal hernia, was found on operation to have within the sac a strangulated Meckel's diverticulum. As it was evidently gangrenous, he resected ten centimeters of the intestine on either side and united the ends by a Murphy button. The recovery was uneventful, except that when the patient left the hospital two months later, the button had not passed.

Intestinal Exclusion.—The definition of this procedure is as follows: The term means the rendering inactive any part of the intestinal canal by surgical means. B. G. A. Moynihan (*Lancet*, October, 1904) states that examples of this exclusion are to be seen when entero-anastomosis is performed. When the intestine is cut across, the distal end closed and the proximal end united to the side of the distal. The following forms of intestinal exclusion are recognized: Entero-anastomosis of Maisonneuve; entero-anastomosis with constriction by suture of the part distal to the upper opening. Unilateral exclusion, when the gut is divided completely across and the proximal end is implanted into the side of the distal. Bilateral exclusion, when the bowel is divided at two places and the intestinal channel is restored, leaving a segment of the bowel detached. Of this segment one end may be left open and stitched to the skin, or both ends may be closed when a fistula exists in the bowel lying between them. The operation may be called for under the following conditions: Tuberculosis or simple ulcers of the intestine which have led to the formation of external fistulæ. In intestinovaginal fistula following hysterectomy, a bilateral exclusion is performed and the sequestrated loop drains into the vagina. In cholecystenterostomy, the gall-bladder is joined to the portion of the bowel cut off by unilateral exclusion. Unilateral exclusion, except in cases of disease, affecting the lower end of the ileum, offers no advantages over lateral anastomosis.

Sterilization of Rubber Gloves.—Washing rubber gloves with hot water and soap for four minutes will not disinfect them, according to the many experiments of D. Fromme and J. Gawronsky (*Münch. med. Woch.*, October 4, 1904). If, however, they are first washed in soap and water and then placed for two minutes in a sublimate solution, germs could never be found on the surface. It is perfectly safe to use the same gloves first for a septic and then an aseptic operation, provided they have no holes and the above precautions are followed. Likewise, it is not necessary to sterilize the gloves at home, since washing them on the hands directly before the operation will be perfectly sufficient.

A Predisposing Cause for Appendicitis.—The following combination of intestinal conditions is responsible for the occurrence of this disease, according to G. Rubin (*Jour. Am. Med. Ass'n*, October 29, 1904). The accumulation of gases below the ileocecal valve and their voluntary retention, the ensuing distention of the cecum and dilatation in various degrees of the cecoappendicular orifice, the entrance into the appendix of larger fecal masses than are readily expelled, the interference with the vascular circulation and resulting erosion of the mucosa of the appendix with subsequent infection. The author made some experiments with a view of corroborating the theory proposed. Portions of bowel about 50 c.c. long, including cecum and appen-

dix, where resected in cadavers of persons dead from diseases other than would affect that part of the intestinal tract. After cleansing the bowel, the colonic end was ligated, small shot, peas and beans were introduced through the ileum end and the bowel manipulated so as to imitate peristalsis. It was observed that none of the bodies entered the appendical cavity, although the appendix was held at the most pendant point. Then the bowel, still containing these materials, was inflated, and the same process of rolling repeated, with the result that in all the experiments, with one exception, the appendix was filled with shot, and in two cases peas of medium size also gained entrance. During the process of inflation, the appendix was also ballooned out, and it is reasonable to suppose that a similar phenomenon might occur in the living subject.

The Early Treatment of Clubfoot.—Most writers on this subject advise beginning treatment as early as possible, at birth or soon after. V. P. GIBNEY (*Am. Med.*, October 29, 1904) differs from this view and doubts the advisability of instituting treatment at this early stage, and prefers waiting until the child is able to walk. Appreciating the ossification periods and all the arguments advanced in favor of early treatment, yet he is not convinced that enough is gained to justify the continued interference with the nutrition of the child at the time when every effort must be directed to perfect the infant feeding and hygiene. The excoriations, strained tendons and ligaments must surely inhibit digestion, and if digestion is inhibited, nutrition cannot satisfactorily proceed. Although he declines to treat clubfoot in young infants until they are able to walk, he does not infer that nothing ought to be done during the first eighteen months. The severe forms of treatment should be mitigated, as it is well known that a large number of cases of moderately high degree are corrected by the hand of the mother. This good work should merely be supplemented by simpler forms of apparatus.

Surgical Reflections on the Diagnosis of Cancer of the Stomach.—A. G. GERSTER (*Medical Record*, October 29, 1904), appeals to general practitioners to take earlier action in case in which the suspicion of gastric carcinoma seems justified. While it is true that the technic of the excision of gastric cancer has been developed to such a degree that the mortality in the hands of some operators, such as Mayo, has been reduced to about eighteen per cent., in the direction of early diagnosis much less progress has been made. We are furthermore confronted by the dilemma that if we wait until the diagnosis is reasonably certain, especially if we delay till a palpable tumor exists, it is too late to expect cure from operation. A reliable diagnosis of cancer of the stomach in the incipient stage, in which it is susceptible of successful operative treatment, is with our present knowledge a sheer impossibility, and therefore in the case in question we must make up our minds to submit the patient to the risk of an operation before the diagnosis is firmly established. The author concludes that when in a clearly progressive case of an intractable disorder of the stomach the local and general symptoms, conscientiously collected and weighed, strongly justify the suspicion of cancer, diagnostic laparotomy should be considered not only admissible, but obligatory.

THERAPEUTICS.

Natural Mineral Waters.—It has been recognized that no chemical analysis, no matter how refined or exhaustive, can determine the exact nature of natural mineral waters, and hence it may be assumed that no artificial mineral water can ever exactly reproduce the true natural water. Years of chemical experience has shown SPRIGGE (*Lancet* Vol. V, No. 4196, 1904, p. 323) that the therapeutic results cannot be duplicated any more than the water itself be manufactured. In a series of investigations conducted in these natural mineral waters, more particularly with Apollinaris, the suggestion is made that these therapeutic differences may in part be due to minute traces of radio-active salts, which are present in many of these natural waters. High pressure and high heat in the bowels of the earth are factors that cannot be reproduced in the chemical laboratory.

Treatment of Exophthalmic Goiter.—Drug treatment for this condition having been practically exhausted, there remains for discussion the surgical treatment, which is divided into the hemisection of the gland and into section of the cervical sympathetic, and the less generally recognized serum treatment. GEORGE R. MURRAY (*Lancet*, August 27, 1904) believes that as there is no good reason for considering that Graves' disease is infective in origin, there can be no good reason why a satisfactory antiserum should not be obtainable. Rather than to prepare the serum by the method of Möbius and Portis, Murray has resorted to the simpler means of feeding rabbits on thyroid extract. He uses ordinary rabbits or Belgian hares. In a series of sera, with which he obtained admirable results, the animals were given an average of seven minims of liquor thyroidei a day from October 18 until November 20. The serum was decanted and carbolized, and the two following cases of exophthalmic goiter were treated with it: The first was a very marked example of the disease, and the patient had been subjected to every known form of treatment, including Möbius' antithyroid serum. None of these had helped her. Under Murray's serum, however, she gained in weight, and the symptoms, which had been very aggravated, became greatly mitigated. The author, however, states that it is not impossible to account for the increase in weight and general improvement from the simple fact that the patient was in the hospital. The second case was that of a girl, nineteen years of age. The serum was given for three weeks. A moderate degree of improvement was noted, so that the author was led to the conclusion that if larger animals were used, this means of preparing sera would undoubtedly be of service, especially in the treatment of very acute cases.

Quinine by Injection.—The treatment of malarial fever by the hypodermic injection of quinine has been recommended by Manson, but rarely employed. A report of its use in 18 cases is made by C. M. FLEURY (*Jour. Royal Army Med. Corps*, October, 1904). He found the most suitable preparation to be "quinina hydrochloricum acidum" of the B. P. It was readily soluble in warm distilled water,—1 minim of water taking up 1 grain of quinine. This preparation was non-irritating. He injected the solution deep into the structures below the ribs on the left side, getting in this way near to the spleen. The amount given was usually 8 grains, but in severe cases 16 were given without any bad effects. The results in almost every case were striking, and where no reaction followed the injection, it was found that the patient was suffering from some disease other than malarial fever. The cases treated

were those who had been residing in India for some time and had constant attacks of fever which failed to respond to the administration of quinine by mouth. The author claims that this is an easy and rapid method of cure, there is no headache, no buzzing in the ears, and the disease is cut short; in only a few instances were more than two injections required.

PATHOLOGY AND BACTERIOLOGY.

Vital Staining of Blood.—A new and superior method of staining blood and demonstrating some of the more delicate structures, has been discovered by H. Rosin and E. Bibergeil (*Zeitsch. f. klin Med.*, Vol. 54, Nos. 3 and 4). An alcoholic solution of an anilin dye is spread over a cover-slip with the edge of a second cover-slip so that a thin, uniform layer is obtained. When dry, a small drop of blood is spread out over the dye in the same manner and then transferred while still moist over the chamber of a hanging-drop slide and the edges hermetically sealed with vaselin. This method enables examination of the blood in very thin layer while still in a fresh or vital condition, and since no other fluid is added, the elements will preserve their shape for weeks. After twenty-four hours the erythrocytes still appear as in the fresh specimen, and after eight days the majority have undergone no change. In the second week the hemoglobin will slowly begin to dissolve. The above applies to normal and chlorotic blood, but in severe secondary or pernicious anemia a disintegration is noticed as early as the second or third day. Acid dyes attach the cells more readily than basic dyes, though eosin is generally well tolerated. Polychromatophilia is well seen, the blue dyes, such as methylene blue and methylene azur being especially well suited. It is generally stated that basophile granulation occurs only in certain pathological conditions, but by the author's method every tenth red cell approximately contains granules which are, however, more delicate than those seen with lead poisoning, etc. There is still considerable dispute as to whether the granules denote degeneration of the protoplasm or disintegration of the nucleus, but the former explanation is more probable, since a mixture of methyl green (three parts of the saturated alcoholic solution) and neutral red (two parts of the saturated alcoholic solution) applied as described above, will stain the nuclei green and the granules red. In older preparations the cell itself has often disappeared so that the granules occur free, while in leucemia the intact, extruded nucleus can often be seen. Both elements retain their behavior toward special stains even in this condition, so that it is difficult to speak of any connection between the two. In fresh specimens of blood the ameboid movement of blood platelets is very evident and an increase in number marked in leucemia. In the stained condition they present a slightly granular center and a colorless protoplasm. The latter soon swells up and forms round or oval rings, leaving behind the center in an excentric position. With eosin and methylene blue the center stains blue and exhibits red granules, which tend toward the periphery. It is probable that he platelets form independent elements of the blood which are not derived from either red or white blood cells, and which stand in intimate relation to coagulation. Similar researches on white cells are promised in a further article. A full bibliography on hematology is appended to the article.

Iodine Reaction of the Blood.—The demonstration of glycogen in the blood has been modified by A. Hirschberg (*Zeitsch f. klin. Med.*, Vol. 54, Nos. 3 and 4) as follows: A thin, uniform smear of blood is made upon a cover-slip and then placed while still moist upon the hollow of a hanging-drop slide containing a small crystal of iodine. The edges are hermetically sealed with vaselin, and the preparation then examined with the oil-immersion lens. In normal blood intracellular glycogen is occasionally found, but extracellular granules are more common and have no diagnostic importance. They are said to be increased in fractures, diabetes and severe anemia, but this is certainly not constant. In catarrhal jaundice small yellow platelets are occasionally seen which are probably blood platelets containing glycogen. The erythrocytes always contain diffuse glycogen, since they stain brown with the new method granules are never found. The intracellular granules of leucocytes never invade the nucleus but often lie grouped about it in the protoplasm. The multinuclear leucocytes are most often affected, and the statement that most cells are especially rich in glycogen is certainly not justified. All attempts to stain iodized blood films, particularly with neutral red, failed, since the iodine vapors fix the blood before the dye has had time to stain the nucleus. With the new method, positive results are often obtained where the older ones fail completely. Some doubt has recently been expressed as to whether the substance in question is readily glycogen, but the reaction toward iodine, the negative behavior toward specific dyes for amyloid, such as methylviolet and the resemblance in structure to the granules of glycogen contained in liver cells, remove all doubt. The reason why glycogen is found more frequently with infection and intoxication is because it is here changed into a less soluble form, so that it resists the action of solvents. The injection of albumin, peptone and carbohydrate, aseptic suppuration, indeed every process accompanied by emigration of the leucocytes, will have the same affect. In the hematopoietic organs, glycogen is also encountered frequently in health with the new method.

Blood-platelets in Human Blood.—The following method is recommended by E. Helder (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 3 and 4) for enumerating the blood-platelets in human blood. A special counting chamber is selected, only 0.02 millimeter high and a special pipette permitting a dilution of 1:30. The blood is diluted in this proportion with a fresh filtered solution of sodium metaphosphate, and then examined in the chamber with the high objective. An even distribution will generally be obtained of the round or oval, highly refractive bodies, whose interior generally contains an eccentric darker area, the nucleus. Their size is one-third to one-half that of the red cells. During health the average number counted was 228,000. A large number of counts were made to ascertain if the same diurnal fluctuations occur as with red and white cells, but with inconstant result. Fasting and the ingestion of food also seems to be without marked influence. In the various forms of anemia, normal or slightly increased figures were obtained. A definite relation between the time of coagulation and the number of platelets is undeniable, for in a case of purpura hemorrhagica they were exceptionally low and increased in number as the patient improved. High figures were found in moderately severe cases of tuberculosis, carcinoma, pulmonary gangrene, empyema, spondylitis posttyphosa, erysipelas, sepsis, pneumonia (after the crisis), typhoid (after the disease is over). In the latter two diseases there is a diminution throughout the course.

Renal Changes in Experimental Hemoglobinuria.—It is a well-known fact that if blood which has been rendered laky, is injected into animals, death may occur in a few minutes. At autopsy, characteristic renal changes will then be found. L. Levy (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 3 and 4) claims that these lesions are caused directly by the free hemoglobin which seems to have a specific action upon the epithelial cells of the convoluted tubules, leading to the formation of hemoglobin casts. It is an interesting fact that the same lesions are found if blood-poisons, such as toluylendiamin are injected, which goes to show that the liberated hemoglobin and not the drug itself, is the toxic agent.

On the Production of a Specific Gastrotoxic Serum.—A research was conducted by C. Bolton (*Proc. Royal Soc.*, September 28, 1904), from two points of view, namely, to add if possible any facts to the knowledge of cytotoxic action, and to throw some light upon the pathology of human gastric ulcer. The following conclusions were arrived at: On either intraperitoneal or subcutaneous injection of the stomach cells (or a fresh extract of them) of the guinea-pig into the rabbit, the blood serum of the latter becomes highly toxic for guinea-pigs. The serum leads to death on injection into the guinea-pig and causes necrosis of the mucous membrane of the stomach, leading to ulceration and hemorrhage. The toxin contained in the serum consists of at least two factors: (1) A specific gastrolysin, which leads to necrosis; (2) hemolysin which assists in producing hemorrhage. The hemolytic factor can be removed, leaving the gastrolytic, which still produces stomach lesions. The gastrolysin is a specific cytotoxin and consists of an immune body and a complement. It does not visibly affect the cells in vitro, and it does not produce necrosis in the stomach of the animal which has elaborated it, possibly owing to the concomitant formation of an anti-immune body. By injection of the stomach cells of the rabbit into the rabbit a gastrolysin is formed which causes necrosis in the guinea-pig's stomach; it therefore possesses at least two cytophilic affinities. By injection of the stomach cells of the guinea-pig into the guinea-pig a gastrolysin is formed which causes necrosis in the stomach of the rabbit; this gastrolysin is probably of a similar nature as the preceding. The importance of the above conclusions with regard to the pathology of human gastric ulcer lies in the fact that an animal can elaborate in its own blood by the absorption of the cells of a similar animal, and, therefore, presumably of its own cells, a toxin which would cause necrosis in the mucous membrane of its own stomach were it not for some deterring influence, probably the concomitant formation of an anti-immune body.

Human Blood-fluids and the Staphylococcus Pyogenes.—It had been determined by Wright and Windsor that normal human blood does not exert upon the staphylococcus any bactericidal action whatever, and that anti-staphylococcus inoculations do not lead to a development of any bactericidal power in the blood. Wright also found that phagocytosis of bacteria is dependent upon an effect exerted upon the bacteria by the blood fluids,—the bacteria being prepared by the latter, for the action of the phagocytes,—and he spoke of this effect as an opsonic effect. A. E. Wright and S. R. Douglas (*Proc. Royal Soc.*, September 28, 1904), further found that the increased phagocytic effect which is obtained with the blood of successfully immunized persons is attributable not to any modification induced in the leucocytes, but to an increased opsonic power in the blood fluids. Normal serum does not exert any characteristic agglutinating action upon the staphylococcus. Such agglutination as is obtained is not very sensibly increased under the influence of staphylococcus inoculations. A low phagocytic power and staphylococcus infection are related to each other by some fact of causation. While it is *a priori* possible that the diminished power which characterizes those infected by the staphylococcus might be the result of the staphylococcus invasion, it is infinitely more probable, in view of the entire absence of clinical symptoms in the slighter cases of staphylococcus infection, that it is the defective phagocytic power of the patient which furnishes to the staphylococcus, which is normally present upon the surface of the body, the opportunity for invading the skin. The authors studied the distribution of the opsonins in the infected organism. Wright and Lamb had found in the case of patients who had succumbed respectively to typhoid and malta fever that the amount of agglutinins in the splenic pulp is invariably less than in the circulating blood, in some instances over 200 times less. Lamb further showed in the case of monkeys examined immediately after the crisis of spirillum fever, that the splenic pulp (where the spirilla still survive after they have disappeared from the circulation) is much poorer in bactericidal and bacteriolytic substances than the circulating blood. It, therefore, appears that he *Bacillus typhosus*, the *Micrococcus melitensis* and the *Spirillus Obermeyeri*, respectively multiply and maintain their existence, within the infected organism in regions of low bacteriotropic pressure. (By "bacteriotropic pressure" is meant the mass effect exerted upon the invading bacteria by the protective substances contained in the blood-fluids). The authors assume that the lowered bacteriotrophic pressure in the nidus, where the micro-organisms are cultivating themselves, results from a retarded replacement of protective substances which are removed from the body-fluids, where these come into contact with bacteria. It may be enunciated as a proposition of general application that the invading micro-organisms cultivate themselves in the organism in regions of lowered bacteriotropic pressure. This is true with respect to staphylococcic infection.

The Action of Colloidal Silver on Toxins in the Blood.—The clinical experience that colloidal silver has a favorable action in various forms of bacteremia, has led H. J. Hamburger and M. J. Hekman (*Arch. Internat. de Physiol.*, July, 1904), to test this result by means of experimented investigation. They studied the effect of collargolum upon the hemolytic power of staphylotoxin. The addition of one-quarter cubic centimeter of a one per cent. solution of collargolum to one cubic centimeter of staphylotoxin serum, prevents hemolysis. On the other hand, doses of one-quarter cubic centimeter of collargolum in concentrations less than one per cent. 1-500, 1-1,000, etc.) to two cubic centimeters of staphylotoxin serum, increases hemolysis. Even a solution of .000001 16 gram of collargolum to 2.5 cubic centimeters of liquid has this favorable effect on hemolysis. The authors attribute the inhibitory action of the greater concentrations of collargolum to some catalytic effect.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

ASEPSIS IN SURGERY.

It is evident that surgery is as yet on the borderland only of the aseptic goal toward which she has been struggling for many years. If we are to believe, as we certainly have every reason to, the sanguine expressions of hope from the mouths and pens of the most eminent operators, the day is perhaps not far distant when we shall have actually reached the aseptic era.

The subject, however, is one to which the theory of limits is so admirably adapted that it must be conceded by all that the perfection ultimately to be reached in this matter will be in the nature of infinitesimal imperfection. That this is true is attested to by the variations in the beliefs of the men who have given the subject profound attention.

A. J. Ochsner, in the *Annals of Surgery* for October, says, "My observations have convinced me that the only form of infection which must be considered in surgery is *contact* infection. This is due to the introduction into the wound of septic material from uncleaned hands, instruments, sponges or dressings, or from speaking or breathing into the wound."

Charles Harrington, of Boston, records in the same journal that during an operation for hernia at one of the principal city hospitals he placed a sterile Petri dish about eight inches from the instruments upon the instrument table. "At the close of the operation the dish was removed and incubated. The result demonstrated that upon each square inch of the dish, and inferentially of the table, and of the instruments thereon, and presumably in the field of operation, no less than 120 organisms, chiefly pus cocci, were deposited from the air in the course of an hour. It is not for me to say how much danger may reside in such a shower of bacteria. Frankly, I do not know, nor does there seem to be any unanimity of opinion on the part of those who have investigated the question of aerial infection."

George H. Monks, in the same number of the *Annals,* remarks: "Whatever may be the actual danger of air infection, direct or indirect, and pending the results of more definite experiments, the demonstrated existence of pathogenic bacteria in the air of large hospitals is presumptive evidence of the necessity of some efforts looking toward their exclusion. Therefore, it is necessary to mop the floor . . . and to minimize drafts from all sources. It is presumably safer also to filter the air."

The conclusions reached from certain experiments with air infection, conducted under the direction of Monks, at the amphitheater of Boston City Hospital, were as follows: At no time in the twenty-four hours was the air free from organisms, the smallest number being found between midnight and seven o'clock in the morning. The vast majority of the organisms were harmless saprophytes, although in some plates of every series staphylococci were found. The streptococcus was found in two instances only.

Chicago is to be congratulated in having in the new and modern Augustana Hospital, as designed by Ochsner, a building in which surgical research can be carried on with satisfaction. Dr. Ochsner is further particularly fortunate in the fact that he has a method of training his assistants, which for perfection of detail is probably to be equaled, in the east, at least, only at the Johns Hopkins Hospital.

The system is based upon the belief that the source of wound infection can be detected only by limiting the number of persons who come in contact with anything which in turn comes in contact with the wound. The staff therefore consists of one operating nurse, one chief assistant, three second assistants, and six third assistants. The present operating nurse has been the sole

nurse assistant for the last 5,000 operations. The chief assistant holds office for three years. He is chosen from the two second assistants, whose term of service is eighteen months. These in turn are chosen from the third assistants, whose term of service is four months. The third assistants take no part in the operating.

It is indeed not to be wondered at that with such a carefully organized corps of assistants Ochsner has been able to carry on the immense amount of excellent work with which he is accredited.

It has sometimes been said, and there is no denying that much truth supports the assertion, that the spirit of surgical investigation is not rife in the city of New York. The profession here has been charged, both seriously and in jest, with commercialism and a tendency to merge the science of surgery into an art. It is not altogether the result of that well-known commercial environment which pervades everything in New York that has led to this unfortunate state of affairs.

There is, we believe, no institution in this city equipped, so far as its corps of assistants go, as well as the hospital of the Mayos', at Rochester, Minn., as the Department of Surgery at Johns Hopkins, or as the Augustana Hospital of Chicago. Why such an institution, based on the lines of these hospitals, has never sprung into being in New York has been a source of astonishment and regret to not a few.

It is to be hoped that the establishment of the Rockefeller Institute for the development of the Science of Medicine will bring into being an organization, along similar lines, for the furtherance of the science of Surgery.

A SPECIFIC PRECIPITIN REACTION IN BOTHRIOCEPHALUS INFECTIONS.

While it is quite generally held at the present time that all forms of pernicious anemia are probably the outcome of definite intoxications, this view has recommended itself especially in the interpretation of the disease accompanying parasitic infections. Experimental research in this direction has, however, been rather meager and largely confined to the study of the *Bothriocephalus* infection.

This parasite, it will be recalled, belongs to the order of tapeworms and is quite common in the lake regions of Switzerland, northern Russia, southern Scandinavia and northern Italy, where infection takes place through certain fish, which are eaten either raw or imperfectly cooked. In the United States only a relatively small number of cases have been reported in the literature, but it is quite likely that the disease is more common among the Scandinavian and Finnish population of our great lake States than is generally supposed.

Regner, in 1889, first demonstrated that the broad tapeworm, as it is also commonly called, can produce the exact clinical picture of the typical pernicious anemia, as described by Biermer, and since then his observations have been abundantly confirmed. As in the case of the hookworm infection, however, anemia does not occur in all individuals who harbor the parasite. Individual peculiarities here exist, the nature of which we are as yet in ignorance.

The first experimental proof of the genetic relationship between *Bothriocephalus* infection and the corresponding anemia was brought by Tallqvist and Schaumann, who succeeded in producing a distinct anemia in dogs by feeding with the freshly obtained tapeworms. Subsequently these same observers showed that the worm possesses distinct hemolytic properties. The most recent researches in this direction come from Kraus's clinic in Berlin and are especially interesting, as they demonstrate that the body of the host contains specific albumins, which are referable to the infecting parasite and have manifestly been absorbed. This has been proven by the demonstration of corresponding precipitins in the blood of the patient. To this end a *Bothriocephalus* extract was prepared by the autolysis of about twenty-five grams of freshly procured proglottides. On bringing one c.c. of the resulting solution together with one c.c. of the patient's blood serum a distinct precipitate then resulted, even in a dilution of the parasitic extract of 1:1,000. Normal blood serum gave no precipitate.

As confirmatory evidence that the precipitin found in the human blood serum was referable to the *Bothriocephalus* infection, a rabbit was further immunized with the worm extract and a corresponding examination made. This showed that the rabbit blood serum now also contained a precipitin, and yielded a precipitate with the worm extract in the dilution of 1:1,000.

It can thus hardly be questioned that absorption of an albuminous substance takes place which is directly derived from the worm. But

on the other hand there are no data available as yet, which would enable us to decide whether this substance is produced during the life of the organism, or whether it is a product of the autolysis of necrobiotic proglottides.

However this may be, the observation is one of great interest and suggests avenues for the investigation of some of the cryptogenetic forms of pernicious anemia also, not to speak of the anemia associated with hookworm infection, material for which is manifestly common enough in some of our Southern States.

RECENT ADVANCES IN TYPHOID FEVER.

At this season of the year, typhoid fever is always the most interesting of affections for the general practitioners of medicine throughout the country. Notwithstanding the definite knowledge that typhoid fever is an easily preventable disease, practically always water-borne, every fall sees a series of at least small epidemics in various cities throughout the country. Most of this is due to the fact that municipal politics are run for the benefit of the politician and not for the benefit of the people.

This seems to be especially the time to recall this fact, for now, with the presidential election over, most physicians will take not the slightest interest in politics, State or national, until another election approaches or, in many cases, even until another presidential election approaches. For those who bewail the unfortunate prevalence of typhoid fever every fall, it might be well to remember, or even to post up in some conspicuous place where they shall see it often, the expression of the modern sanitarian who said "whenever an individual dies of typhoid fever, some one should be hung."

In the meantime typhoid fever, like the poor, we always have with us, and so advances in our knowledge of the disease continue to be of enduring, or at least of ever-recurring interest.

One of the most recent bits of progress is the discovery that certain formamides, notably urotropin and its allies, if administered to the patient shortly before the blood specimen is taken for examination by the Widal reaction, will almost surely give rise to agglutination. Whether the patient has had typhoid fever or not, or is suffering from it at the present moment, cannot therefore be decided with any certainty if urotropin has been administered within twenty-four hours. Needless to say this, if found to be generally applicable, is of much moment. It is now fairly understood that in a certain number of so-called abortive cases of typhoid fever, in which the diagnosis has even been substantiated by a positive Widal test, the case has really been one of slight febrile disturbance, due not infrequently to intestinal indigestion, but not at all to the presence of the typhoid bacillus. The disturbing factors in the bacteriological diagnosis of such cases are probably many in number and they need further investigation.

With regard to the treatment of typhoid fever, the advances have been very limited. No new remedy has been suggested within the year that has seemed to promise to be of any enduring benefit. With regard to the feeding of typhoid fever patients, however, there has come a modification of the general persuasion as the necessity for an exclusive milk diet and a deprecation of the too great limitation of food, either in amount or variety. Liquid food is of course absolutely an indication of the disease. This need not necessarily, however, consist only of milk or even be composed mainly of milk. There are not a few persons who do not like milk, who cannot take it without a certain amount of disgust and in whom it constantly, even in health, produces a feeling of discomfort. Their digestive nature does not change because they happen to have acquired typhoid fever. It is an excellent dietary rule that declares that articles of diet which are unpleasant for the patient are not well digested and do not prove as nutritious as they otherwise would. To force such patients to take large quantities of milk is almost surely to initiate a disturbance of equilibrium of the intestines that is eminently undesirable under the pathological conditions present.

There are those who insist that not a few of the cases of persistent tympanites in typhoid fever will be found to occur in patients who have an initial dislike for milk yet have been persuaded much against their will to try and take it as an exclusive article of diet. For such cases a certain amount of milk modified in various ways by the addition of lime water, or of barley water, or of a tablespoonful of coffee to the glass may prove to be readily digested. Other liquid foods, however, such as simple soups, into which an egg has been stirred, or pea soups and various thin broths should be used frequently as a relief from the monotony of an

otherwise exclusive milk diet. Where such precautions are not taken, it sometimes happens that so little of the milk is absorbed that the good old rule of feeding a fever, announced nearly a century ago, in the face of much opposition, by Graves, fails to be followed since so little of the material taken is absorbed. The result is a loss of strength that augurs ill for the issue.

The real advance in the treatment in typhoid fever that has come consists in the prompt, surgical intervention for perforation of the intestines. Whenever a typhoid patient suffers from any sudden change, a surgeon should be called in consultation. If the change noted begins with pain, however passing the painful condition may be, then very little more is needed to justify at least exploratory laparotomy Any disturbance of pulse or of temperature in addition, should be the signal for the surgeon being placed in charge of the case and being allowed to assume the responsibility. Hesitation or delay in this matter is almost sure to be fatal. It is the old problem of appendicitis over again. A very large part of the death-rate from typhoid fever is due to perforation and at least one-half the cases can be saved by prompt surgical measures. Hence the necessity for keeping the patient at all times under the eye of a trained attendant who shall report at once any sudden change in condition. There must be no waiting until the morning visit or the risk is almost sure to be serious. In strong individuals, immediate operation will not only prove life saving, but will usually enable the patient to react so promptly that the typhoid fever will run its normal course to convalescence without any disturbance or delay.

Unfortunately there is one difficulty with regard to this very promising aspect of surgical intervention for perforation. In a certain number of reported cases all the symptoms of perforation have been present, yet at operation no perforation could be found. Later on, at autopsy, it has been found that the intestine has not been ruptured, but swelling of the mesenteric glands has occurred and that this had caused local suppuration with adhesive peritonitis affecting certain coils of the intestine and thus caused serious disturbance of peristalsis. These cases are thought to be very rare, but since attention was first called to them, every little while sees the report of another one. It is clear that where perforation cannot be found, ruptured mesenteric glands should be looked for and their contents removed as far as is possible and consistent with the patient's condition.

ECHOES AND NEWS.

NEW YORK.

The Society of Medical Jurisprudence.—The 184th Regular Meeting was held Monday evening, November 14. Charles Greene Cumston, M.D., of Boston, Mass., read the paper of the evening, entitled "Remarks on the Jurisprudence of Civil Malpractice, Based Chiefly on the Decisions Rendered by French Courts." Collation after the meeting.

Harvard Medical Society.—The Harvard Medical Society of New York City wishes to announce that Professor Theobald Smith, of Harvard University, will deliver an address upon "The Place of Research in the University Medical School," in Hosack Hall, New York Academy of Medicine, November 26, at 8:30 P.M. Members of the medical profession are cordially invited to attend.

Dr. Bolton Leaves Hartford.—The private sanatorium, established by the late Dr. C. M. Kittredge, was reopened November 1, under the direct care and supervision of Dr. James R. Bolton, formerly of the Hartford Retreat. Kingston, N. Y., is his address.

Dr. Packer at River Crest.—Dr. Flavius Packer, announces his removal to the River Crest Sanitorium, Astoria, L. I., as physician in charge.

French Hospital Open.—The new hospital of the French Benevolent Society, at 450 to 458 West Thirty-fourth Street, was opened Monday by M. Jusserand, the French Ambassador. Representatives of the Governments of Greece and Russia, and a distinguished company of Franco-Americans also were present. M. Jusserand formally declared the hospital open, after the many visitors had had an opportunity to inspect it throughout, and in the process had bought many roses at $1 each from many pretty flower girls. There was no extended speechmaking, but President Maillard, of the Benevolent Society, had a little something to say in introducing M. Jusserand. It was, in part, as follows: "We have dreamed to possess, in this great commercial metropolis of the world, a hospital establishment in keeping with France, which, if not better ordained than the one we already had to meet the necessities of growing usefulness, at least was large enough to render all the services incumbent thereupon—better provided, according to the most recent data of hygiene and the progress of science, and in accordance with the new municipal requirements always strictly to be adhered to; in short, a hospital really worthy of the French flag which we are so proud to float. What of the effort consumed? The end is attained! On new foundations, which, more solid, absorb the old ones, we have constructed a beautiful edifice, and, while meeting the needs of the present, we have perhaps more broadly than is generally done in such cases assured the future." The French Benevolent Society, in its different services, out-of-door assistance, dispensary, etc., and in its hospital, is nonsectarian, and relies purely for the support of its charities upon public donations. Most of the patients treated in the hospital are treated free of charge. To obtain the funds necessary for the new

hospital, the society, which had only about $100,000, made an appeal, and as the French Government headed the list of subscriptions with 100,000 francs, $100,000 was quickly raised. Since that subscription, a legacy and the sale of the Gobelin tapestry, also donated by the French Government, have brought the total to $225,000. The hospital has cost $400,000, leaving a mortgage of $175,000, which the Board of Administrators feel able to carry. The hospital is the third of its name, and will be open for the reception of patients on Tuesday. The first hospital was started in 1881, at 131 West Fourteenth Street, the second in 1888, at 320 and 322 West Thirty-fourth Street. The patients now there will be transferred to the new hospital, 450 to 458 West Thirty-fourth Street. The new building is seven stories in height, with a façade of red brick and limestone, and is 104 feet in length. The driveway is covered. Two floors are given up to private rooms and small wards, and two are used for the large medical and surgical wards. The operating rooms, the pathological laboratory, and the quarters of the house doctors occupy another floor. The top floor is absolutely isolated. It contains the wards for consumption and other contagious diseases.

Society for Psychic Research.—Prof. James H. Hyslop has written a long letter to the *Tribune*, setting forth the aims of the above society and asking for public contributions to aid in further investigation of psychic phenomena. He says in part: "An important institute intended to be of a national character has been founded in this city for the purpose of organizing certain scientific investigations while it conducts in one of its fields a system of philanthropic work. Its needs are the subject of this brief explanation. It has been incorporated as the American Institute for Scientific Research. It is not to be associated with any form of teaching or propagandism, whether philosophical, scientific or religious, but is modeled after the Carnegie Institution, except that it will be permanently limited to a definite field of work, comprising two more or less distinct classes of phenomena. Modeled as it is after the institution mentioned, the institute will not engage directly in investigations, but will supervise endowments and subsidies for such men and bodies of men as are qualified to conduct philanthropy and investigation in the fields which our work is to occupy. But as the two departments of work are somewhat different, only one of them offering opportunities for philanthropy, it will be necessary to consider them apart. The two fields comprehend abnormal and alleged supernormal psychology, or psychic research. As soon as possible the institute would provide a proper clinic for study and therapeutic treatment of certain types of functional mental disease, insanity, hallucination, secondary personality, and such troubles as may be made to yield to hypnotic suggestion. The type of institution here in mind is that of the Salpêtriere, under Pierre Janet, or the Clinic of Berillon, in Paris. At present it is well-nigh impossible, owing to the absurd misconception of the subject by the public, though they favor its use when other methods fail or when it is wise to employ it."

PHILADELPHIA.

Cancer Hospital Receives Charter.—A charter has been granted to the incorporators of the American Oncologic Hospital for the treatment of cancer and other tumors. Generous contributions are being made for the erection of buildings, and a committee is deciding on a site for the institution.

Celebrates 134th Birthday.—Mary McDonald, an inmate of the Home for Aged and Infirm Colored Persons, celebrated on November 14 her 134th birthday. What appear to be authoritative records confirm the age of this remarkable old lady. She has been blind for two years, but still retains many of her faculties. During the past year she has failed perceptibly, and now spends nearly all of her time in sleep.

The Schott Treatment of Diseases of the Heart and Blood Vessels.—At the Philadelphia County Medical Society, November 9, Dr. J. M. Anders gave his impression of this treatment as obtained by personal observation at Bad-Nauheim. He says that physicians abroad and in this country have only a vague idea of the proper cases for this treatment. On the whole, he was very favorably impressed by the results obtained in certain cases, and he is fully in accord with the principles of the treatment. Among the cases observed were two of acute dilatation of the heart coming on during an attack of valvulitis; in these the treatment resulted in complete restoration to the normal. A third case was one of failure of compensation in valvulitis, and a fourth was an instance of chronic valvulitis. A fifth case was an illustration of a certain class of cases in which digitalis loses its effect and after a course of the baths again exerts its action.

The Schott Treatment at Home.—Dr. James Tyson said he would employ the Schott method more often were it not for the difficulty in carrying it out at the patient's home. The baths can be used in a private house, but a helper is needed the same as for the exercises. There was for a time a man and also a woman in Philadelphia who could superintend the baths and exercises, but the demand for their services was so small that they could not continue at the work. The action of the carbonic acid is the most difficult to imitate at home. In chronic or acute dilatation, partial recoveries are obtained by the Schott treatment, and in some cases too far advanced to send to Nauheim, much good may be secured from home treatment. Dr. Tyson has not availed himself fully of the exercises, preferring to use the baths until as much good as possible has been accomplished by them, and then adding the resistance movements. The baths are contraindicated in cases of dropsy, effusions and other collections of fluid. A practical way of regulating the baths is to desist if the patient feels more uncomfortable after using them; when relief is experienced they should be continued. A very essential point is that in winter the baths should be taken in a warm room.

Technic of the Baths.—Dr. S. Solis-Cohen said there were in Philadelphia people trained in the administration of the treatment in question, and also establishments where they can be cared for. The baths can be given at home if care in the technic be employed. A good plan is to put in the tub half of the water to be employed, having this as hot as possible. The sodium bicarbonate and salt should then be put in and left for twenty minutes. Water of a temperature to make the entire amount comfortable should then be added in the required quantity and finally the acid sulphite, which will give a profuse effervescence. In this way can be obtained results almost as good as those secured at Nauheim. Dr. Cohen gives courses of six or eight

weeks, and then interrupts for eight or twelve weeks, this being followed by a repetition of the course. The baths are given at night before the patient retires, and on alternate days, the intervening days being devoted to the resistance exercises. This treatment will do good in exophthalmic goiter, but may be of great danger to the patient. In this disease, Dr. Cohen would not trust an attendant with the supervision of the treatment.

Study of the Nervous System in Congenital Deformities.—At the Pathological Society, November 10, Dr. D. J. McCarthy presented specimens taken from a puppy that was born with both hind feet turned up and in, presenting a form of clubfeet. Elaborate studies of the spinal cord have been made and later the peripheral nerves will be examined. The lumbar segment of the cord corresponding to the areas of deformity showed marked degenerative changes involving the ganglion cells and also the posterior columns. Above and below this segment were conspicuous areas of hemorrhage. Secondary degeneration above the lesion was pronounced. A noteworthy feature was that of the ganglion cells giving the reaction for iron, showing that they had absorbed hemoglobin.

Erosive Gastritis.—Dr. John Funke exhibited specimens from a case of chronic gastritis with extensive erosions. The lesions were situated mostly along the lesser curvature, and especially in the region of the pylorus. The greater number were between the folds of the mucosa; they varied from one millimeter to one centimeter in diameter, and from one to two and a half millimeters in depth. Dr. Funke does not regard this condition as a forerunner of gastric ulcer, the two being in no way dependent upon each other. Erosion of the gastric mucosa is not considered an entity, as it is, as a rule, concomitant with diseases of the mucous membrane of the stomach. The condition is analogous to ulcerative stomatitis or colitis. The erosions are not necessarily due to the action of the gastric juice, usually resulting from superficial necrosis. Areas of infection following embolism or thrombosis may undergo auto-digestion, but such occurrence is rare. The secretion of substances into the stomach may also be responsible for alterations in the mucosa.

CHICAGO.

Vaccine Virus.—Owing to the great demand for vaccine virus, which, it is said, has caused some producers to place unripe lymph on the market, the Health Commissioner has tendered to all producers of vaccine the services and facilities of the laboratory of the Health Department, and of its expert clinicians, in the bacterial and clinical examinations of all their vaccine products offered for sale and use in Chicago. All vaccine submitted for such examinations, and found to be pure—that is, free from disease-producing organisms, and potent—that is, producing not less than 90 per cent. of successful primary vaccinations—will be so certified by the Department. Defects in either respect will be duly notified.

Money for Hospitals.—The will of Moses Bensinger devises $1,000 to the Michael Reese Hospital and $500 to the Alexian Brothers' Hospital.

Diagnosis of Malignant Abdominal Tumors.—Dr. G. W. Green read a paper on this subject before a recent meeting of the North Branch of the Chicago Medical Society, in which he summarized thus: (1) It is very important for the general practitioner to be a good diagnostician of malignant abdominal tumors. (2) Know the normal anatomy of the abdominal cavity. (3) Trace all tumors to the organs from which they spring. (4) Gastric carcinoma are the most frequent malignant abdominal tumors, and spring from old unhealed ulcers, which could have been cured by a previous operation for gastric ulcer. (5) Uterine carcinoma of the cervix springs from lacerated cervices previously unrepaired. These should have been repaired. (6) If in doubt about the malignancy of any abdominal tumor, give the patient the benefit of the doubt, make an exploratory laparotomy and see.

CANADA.

Quarterly Meeting of the Ontario Board of Health.—The Ontario Board of Health was in quarterly session last week in Toronto, when it was reported that two counties were going to avail themselves of the bonus promised by the legislature to groups ot counties who would undertake to erect and maintain sanitoria for consumptives. If this is decided upon by the counties of Oxford and Waterloo, other counties will doubtless soon fall into line and Ontario will be putting up a stiff fight against the great white plague. The Board passed a resolution expressing hearty sympathy with the Canadian Association for the Prevention of Tuberculosis, which is endeavoring to secure the establishment by the Dominion Government of a sanitarium in each province. The report of the secretary for the quarter showed that there had been 412 deaths in Ontario from tuberculosis during the quarter ending September 3, an increase of 20 per cent. over the corresponding quarter of last year. The deaths from all causes totaled 5,872, compared with 5,893 for the corresponding quarter of 1903. The report also showed that here had been a marked increase in typhoid fever throughout the province during the past quarter, and a decrease in diphtheria.

Vaccination Popular in Montreal.—The Medical Health Officer of Montreal, Dr. Laberge, for 1903 shows that out of 90 cases of smallpox reported in that city during 1903, not even one person suffered from the disease who had been vaccinated during the past five years. Speaking of his report the Medical Health Officer says that it has been proven by experience in Montreal that persons who get vaccinated are practically immune from taking the disease. He also states that he has knowledge that persons who had been vaccinated when they were children, and who had contracted the disease later in life had suffered very little from it. He was glad to say also that Montreal was now a much better vaccinated city than it was many years ago. At the present time the Health Department of Montreal has the cooperation of all schools and factories in the city in order to enforce vaccination. At one time the charge was made that Montreal was a good place to go to if one wished to contract smallpox. The civic officials, who are at present going the rounds of the schools performing vaccination, report that they are meeting with no opposition, whereas two years ago, when the same officials visited the schools, there were 1,000 children who refused to attend school because they had to submit to vaccination. At the 1st of January, 1903, there were five cases of smallpox in the smallpox hospital, and there were ninety other patients admitted during 1903. The deaths number two, and there remained in the hospital on the 31st of December one patient. Of

this number admitted the males numbered 41 adults and 11 minors; females, 26 adults and 12 minors. The number of these vaccinated since five years was nil. The number vaccinated some years ago, 13, while 77 had never been vaccinated.

Montreal Endeavoring to Lessen Spread of Consumption.—The City Council of Montreal has decided to adopt the following by-law prohibiting spitting on sidewalks and in public places, having in view the object of preventing as far as possible the spread of consumption in that city. "No person shall spit upon the floor of any railway car, street car or other public conveyance, or upon the floor of any public building, theater, church, opera house, music hall or hall used for public meetings; railway or steamboat stations or waiting rooms or other public hall, building, room or place, or upon any platform surrounding, in front of, or in the immediate vicinity of any such place, or upon any sidewalk or covered way within the limits of the city of Montreal."

The Care of the Insane in Ontario.—The Provincial Secretary of Ontario, through the Inspector of Prisons and Public Charities, Dr. R. W. Bruce Smith, of Toronto, has given instructions that each jailer in the province of Ontario shall make a special report to the Department on the first day of each month giving the names of all persons confined in the jails of the province who have been certified by the jail surgeon to be insane. The sheriff of each county in the province has also been requested to make a similar return on the first of each month to the medical superintendent of the asylum for the insane for the district in which that jail is located. The Department of the provincial secretary is at the present time removing from the jails and placing in the asylums all those persons who are suitable for asylum treatment. Thus those arrested for insanity hereafter will not be forced to remain in the common jails, as there is now sufficient accommodation in the asylums of the province.

Toronto's New Consumption Hospital.—On September 2 the first patient was admitted to the Toronto Free Hospital for Consumptives, situated about ten miles from the city. Already the number admitted has attained to forty and no case is refused because of inability to pay. Building operations, however, are still in progress as the institution is not yet completed. Surrounding the hospital is an area of rising land forty acres in extent, beautifully wooded. The hospital is conducted under the auspices of the National Sanitarium Association, and will be maintained by the per diem allowance allowed by the city of Toronto, by a Government grant and private subscriptions. Dr. Allan H. Adams is the physician-in-charge.

Staff Changes in the Ontario Asylums.—Dr. R. W. Bell, second assistant physician at the Asylum for the Insane at London, Ontario, has been appointed to the position of medical inspector of the Provincial Board of Health of Ontario. His position at London has been filled by the transfer of Dr. W. C. Herriman from the Kingston Asylum, and Dr. MacNaughton, of London, has been transferred to Kingston. Dr. W. P. St. Charles, of the Mimico Asylum, has been appointed to the position of relieving officer to the public institutions of Ontario and Dr. George M. Biggs has succeeded him. Dr. W. T. Wilson, third assistant physician at the Hamilton Asylum, has been transferred to London to succeed Dr. MacNaughton.

GENERAL.

Surgeons at Pan-American Congress.—Dr. Rudolph Matas, Secretary of the Section of General Surgery for the United States, asks those who wish to contribute papers, to send titles to him at No. 2255 St. Charles Avenue, New Orleans. He also announces that the United Fruit Company's agents are offering as a special inducement to American congressists a reduction of the regular fare for the round-trip from New Orleans to the Isthmus to $50, that is, $25 each way. The steamers leave New Orleans every Friday: the last steamer to leave New Orleans in time for the opening of the Congress will sail on December 30, 1904, at 11 A.M. It takes about four and one-half days to reach Colon and seven days on the return trip on account of a stop-over at Port Limon, where ample opportunity is given to tourists to visit San Jose, the beautiful capital of Costa Rica—"the Paris of Central America"—where the most picturesque tropical scenery can be seen at this season, under the most favorable conditions.

The National Association for the Study of Epilepsy and the Care and Treatment of Epileptics.—The fourth annual meeting of this Association will be held in the Medical Library "The Fenway," Boston, Mass., on November 22. The first session will begin at 2:30 P.M., the second at 8:00 o'clock in the evening. All persons interested in the welfare of epileptics and in charity work generally, are cordially invited to attend the meetings. The following program is announced: Presidential Address, by William N. Bullard, M.D., of Boston; The State's Relation to the Epileptic, by Owen Copp, M.D., Executive Officer of the Massachusetts Board of Insanity, Boston; The Prognosis of Epilepsy, by William Alden Turner, M.D., of London, England; The Influence of Puberty and Adolescence in the Etiology of Epilepsy, by William P. Spratling, M.D., of Sonyea, N. Y.; Certain Aspects of the Differential Diagnosis Between Hysteria and Epilepsy, by Drs. Putnam and Waterman, of Boston; Some Observations on the Treatment of Epilepsy, by Daniel R. Brower, M.D., of Chicago, Ill.; Spectrum Analysis of the Blood in Epilepsy, by J. W. Wherry, M.D., of Clarinda, Iowa; Syphilitic Epilepsy, by Abner Post, M.D., of Boston; (*a*) Observations on Blood Pressure in the Epileptic, (*b*) Lantern Slide Illustrations of Cases, and of the Massachusetts Hospital for Epileptics, by Dr. Everett Flood, of Palmer, Mass.; Ten Cases on Special Treatment, by Drs. Morton and Green, of Palmer, Mass.; (*a*) Salt Poor Diet, (*b*) Reflexes in Epilepsy, (*c*) Status Epilepticus, by Dr. Morton; Lumbar Puncture in Status Epilepticus, by Dr. Morton; (*a*) Myoclonus Epilepsy, (*b*) Exhaustion Paralysis, by Dr. Hoskins, of Palmer, Mass.; Private Colonies for Epileptics, by Dr. E. A. Sharp, of New York; Duties of the State with Reference to Epileptics, by Dr. Max Mailhouse, of New Haven, Conn.; Dietary in Epilepsy, by Dr. L. P. Clark, of New York.

Tests for Cold Storage Food.—Dr. Harvey W. Wiley, the government chemist, who has discovered that nearly every kind of modern food is filled with deleterious substances, has turned now to the investigation of cold storage foods. He has on hand a fine assortment of provisions which have been for a long term in the cold storage plant of the West Point Military Academy. Dr. Wiley's idea is to give this food to one or more persons and to observe its effect upon the normal system. "In testing cold storage food, chemical analysis must be relegated to the rear," said Dr. Wiley. "The sense of taste alone can guide the expert in cold storage products. Therefore, I have made up my mind to be one of the jury of epicures to sit in judgment upon the cold storage food. What we want is a man, with a delicate memory—a man who when he takes his first bite of beefsteak that has been in the ammonia tank

for three years has an overpowering gift of remembrance which will carry him back retrospectively to an occasion when he sat down to a juicy, done to perfection tenderloin."

Beverage Statistics.—France drinks the most wine and Belgium the most beer. The United States as a consumer of spirits, beer and wine runs far behind most countries. The monthly summary of commerce and finance, issued by the Department of Commerce and Labor, says: "France shows the heaviest consumption of the most concentrated beverage spirits, viz., 2.51 gallons per inhabitant. The other countries following in the order of their per capita consumption of spirits, are: Sweden, 2.13 gallons; Germany, 2.11 gallons; Belgium, 1.42 gallons; United Kingdom, 1.38 gallons; United States, 1.33 gallons; Russia, 1.29 gallons, and Italy, .34 gallons. The figures per capita of beer consumption reveal the fact that Belgium stands at the head of the nations, its per capita consumption being 56.59 gallons; second in order is the United Kingdom, with 35.42 gallons, while Germany, which shows the largest absolute figures of consumption, in the matter of per capita consumption, takes third place, with 30.77 gallons; the United States follows with 18.04 gallons. The consumption of wine may be said to be concentrated in two countries, chiefly France and Italy. The figures of per capita consumption in these countries—34.73 gallons in France and 31.86 gallons in Italy—are almost identical with those shown for beer by the United Kingdom and Germany.

Christian Science as a Disease Spreader.—Nothing could better illustrate the truth of our frequent contention, writes the New York *Times*, that "Christian Science" is a deadly menace to every person in every community in which the cult has a single follower than did the account we printed yesterday of what has just happened up in Stamford. The facts are worth repeating: In one of the public schools there, a week ago Monday, a boy of twelve was seen by his teacher to be suffering from fever and headache and was sent home in the expectation that he would receive the care he obviously needed. He did not get it. Instead of calling a doctor or even resorting to familiar household remedies, the mother summoned an Eddyite "healer" and the two undertook to convince the boy by the usual mummery and gibberish that he wasn't and couldn't be ill. This was kept up for days until finally the neighbors, concluding from what little they could learn that the boy had diphtheria, notified the authorities of the city. Then, on Saturday, a health officer forced his way into the house against the protests of its occupants. He found the boy dying of diphtheria and two other children suffering from the disease. Further investigation showed that a child of the "healer" was also suffering from it. A doctor was then called in, but it was too late to save the boy first attacked and he died on Sunday. From Monday till Saturday not the slightest precaution had been taken to prevent the spread of infection, and no use had been made of the beneficent discovery which has in recent years reduced diphtheria mortality from about 75 per cent. to 5 or 6—among the children of parents who believe in a science that needs no quotation marks. Perhaps the boy would have died with the best of care, but his chances of recovery would have been vastly increased if his mother had been a sane woman, no matter how poor or ignorant, and Stamford would not now be threatened with a serious epidemic among its children. It is incidents like this one that cause us to be filled with angry impatience when people say that the "Christian Scientists" are an excellent, well-meaning folk, even if they are sadly mistaken in their theological and philosophical notions, and that at worst they hurt nobody except themselves. As a matter of fact, every one of them is a public enemy, threatening death to all with whom they come in contact and to many who do not go anywhere near them. Yet one of the dispatches from Stamford says, that as the Litchfield child died while under the care of a physician and the death certificate is regular, it is not likely that any proceedings will be taken!

OBITUARY.

Dr. HARRY E. ALLISON, Medical Superintendent of the Matteawan State Hospital, died at Newburg, N. Y., November 12, after an illness of three weeks. Bright's disease caused his death. He was born on December 1, 1851, at Concord, N. H., and graduated from Dartmouth in 1875. Among his classmates was Frank S. Black, ex-Governor of New York. In June, 1878, he received a degree of M.D. and became assistant physician at Willard Asylum, Ovid, N. Y. He took a postgraduate course at the New York Polyclinic, and in July, 1889, he was appointed Medical Superintendent of the State Asylum for Criminal Insane at Auburn. He was appointed a member of the commission to found a new asylum for insane criminals at Matteawan, and on its completion, in 1892, the inmates of the old Auburn asylum were transferred there. Dr. Allison became Medical Superintendent and Treasurer, and held the place until his death.

CORRESPONDENCE.

TREATMENT OF SCARLET FEVER.

To the Editor of the MEDICAL NEWS:

SIR:—Your October 29 issue contains a paper by Dr. Henry L. K. Shaw, of Albany, N. Y., on "The Treatment of Scarlet Fever with the Moser Antistreptococcus Serum," in which the statement is made that Baginsky gave Aronson's Antistreptococcus Serum a thorough trial without satisfactory effects. This is, however, an error, as Prof. Baginsky reported in the *Berliner klinische Wochenschrift*, Nos. 48 and 49, 1902, as follows: "With the new and more concentrated serum prepared by Aronson, which never produced untoward effects, the temperature fell slowly but surely even in severe cases, the patients whose condition was serious from the first finally convalesced undisturbed by complications. This improved serum was injected in 34 cases, of which two died, a mortality of six per cent.; but in view of the small number of cases not much importance is attributed to this reduced death-rate. While the serum does not exhibit the overwhelming effect of diphtheria antitoxin, its action, though slow, is sure and continuous."

Prof. Baginsky says that he used the serum only after animal experiments made by Dr. Paul Sommerfeld, of his hospital, had shown its harmlessness and efficacy. Dr. Shaw also errs in stating that "Aronson obtained a serum from the throats of scarlet fever patients, which were passed through animals until they reached a high virulence, similar to the method employed by Marmorek." Aronson's serum contains, besides the portion produced by immunizing horses with highly virulent animal-passed streptococci, another portion which cannot be computed, and which is obtained by treating horses with streptococci cultivated from severe human cases without animal passage. This differs very considerable in mode of preparation from all the sera hitherto produced.

Prof. Baginsky did not, as is stated in Dr. Shaw's report, say that "scarlet fever is primarily due to the streptococcus;" he merely says that he "found streptococci in 606 out of 701 cases and in 100 autopsies, so

that the importance of these bacteria in scarlet fever is evident." Yours respectfully,

Schering & Glatz.

New York, October 31, 1904.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-Urinary Diseases.

Stated Meeting, held October 19, 1904.

The President, James Pedersen, M.D., in the Chair.

Perineal Prostatectomy.—Dr. F. Tilden Brown presented this subject. The patient, a retired merchant, sixty-two years old, was admitted to the Presbyterian Hospital on July 14, 1904. His brother died of consumption, otherwise his family history was negative. The patient had indulged moderately in alcohol and tobacco, and had always suffered from constipation. He denied gonorrhea and syphilis. He was sexually active up to twelve years ago, but had since been impotent.

During the past ten years there had been a gradual increase in the following symptoms: Frequency of micturition, the patient now getting up three to five times at night to pass small quantities of urine. The urine cloudy, sometimes ammoniacal in odor. Difficulty in starting stream; poor force; dribbling at end. Consciousness of incomplete evacuation, with occasional burning pain during the act. Three years ago he had an attack of acute retention, which was relieved without operation. Later, double vasectomy was done at Smith's Infirmary. He was catheterized for two months afterward, and no catheter was again passed until seventeen months ago, when he had another attack of acute retention. A physician was called, who made an unsuccessful attempt at catheterization, which resulted in moderate bleeding from the urethra. The patient was then referred to the Presbyterian Hospital.

The patient was a large, strong, well-nourished man, showing no evidence of anemia. On admission he was nervous and anxious, and evidently suffering great pain. The bladder extended up to the umbilicus, and was palpable as a tense, rounded mass. Rectal examination revealed an enormously hypertrophied prostate, and bimanual examination after superpubic vesical puncture indicated that most of the tumor was intravesical. The patient had not been able to void urine for twenty-four hours. After an unsuccessful attempt to enter the bladder with catheters of various shapes and composition, a large curved trocar and canula was introduced, and about 30 ounces of brownish, somewhat turbid urine evacuated. A No. 18 F. soft catheter was introduced through the canula and left *in situ by* suturing it to the skin.

Three days after admission perineal prostatectomy was done through an inverted Y-incision. The patient made an uneventful recovery, and was discharged from the hospital on August 27. On October 18 he reported that he had passed a few calculi since leaving the hospital. He was feeling and looking well, and was urinating about every three hours. The urine was still cloudy. There was never more than three drams of residual urine. The patient's impotence had not been improved by the operation.

Dr. Brown presented another patient with this same affection, who was a stage manager by occupation, born in Italy fifty-three years ago, and was admitted to Bellevue Hospital on March 4, 1904. His family history was negative. He had always been well until his eighteenth year, when through embarrassment he would hold his urine until he could scarcely pass it. This habit persisted for about ten years. Two years ago he had an attack of retention of urine, for which he was treated at the Columbus Hospital. He was catheterized twice daily for the first three or four days, and gradually recovered control of his bladder, and could pass urine fairly well, but suffered from a burning sensation after urination. Eight days ago, after a period of constipation, he was unable to void urine, and began to have severe pain in his bladder. On his admission to Bellevue, 26 ounces of urine were withdrawn with the catheter, and 22 ounces later in the day. He occasionally passed some urine voluntarily, and without pain. Rectal examination revealed marked enlargement of each lateral lobe, with interlobular furrow. Cystoscopic examination showed very prominent lateral prostatic lobes. On March 11 perineal prostatectomy was done through an inverted Y-incision and the enlarged lateral lobes removed. A perineal drainage tube was inserted and the right half of the wound closed. The patient had an uninterrupted convalescence, and when he left the hospital, on May 5, his perineal wound was closed; he was voiding urine at normal intervals, and the catheter test showed that there was no residuum.

Suprapubic Prostatectomy.—This was the subject of Dr. Willy Meyer. The patient was a man, seventy-four years old, who came under his care last May. About two years ago he developed hematuria, which was rather persistent, and had to resort to the use of the catheter. His symptoms gradually became more aggravated, and when Dr. Meyer first saw him he was passing the catheter hourly, day and night, and still oftener. He was greatly reduced in flesh and strength, and gave a history of having had several attacks of urethral fever. For six months there had been total retention. Examination per rectum revealed pretty high up a not specially enlarged prostate, the left lobe being slightly larger than the right. The urine was strongly alkaline, and had a fetid odor. The cystoscope, which was introduced with some difficulty, disclosed papillomatous excrescences on the surface of a projecting mass above the internal urethral orifice. Whether this mass represented a tumor or a middle lobe of the prostate, could not be said with certainty. On May 12, 1904, upon opening the bladder above the pubes, a rather confusing picture was presented. There was that mass directly above the left half of the internal orifice of the urethra, sessile, with a broad base, projecting into the lumen of the bladder. On its surface appeared that papillomatous growth, with phosphatic incrustations, as seen through the cystoscope. Paquelin's cautery was used to extirpate it. Soon, however, the whitish tissue of prostatic adenomata were visible, whereupon both lobes of the prostate were shelled out with ease. The remaining cavity was packed with sterile gauze, the greater part of the vesical wound sutured, and a tube left in the bladder wound. The patient made a good recovery, excepting that between the twelfth and sixteenth day he developed a hematuria, such as occasionally followed the Bottini operation. He gained rapidly in weight, and the frequency diminished, so that he

now passed his urine every three or four hours during the day and once or twice at night. He was able to completely empty his bladder. His sexual power was preserved.

Dr. Meyer said he still is a strong advocate of the Bottini operation in certain cases of prostatic overgrowth. In the face of a good deal of opposition he had continued to do that operation for five years, the time originally set down by him for the rough trial in order to help decide whether or not it deserved a permanent place in the surgery of the prostate. During those five years he had done the operation 59 times, twice only within the last two years. As in other surgical diseases, he found that no one method was suitable to all cases. He now tried to separate them, and decide in each instance whether to operate by the perineal incision, or by the suprapubic, or by the Bottini method. Those cases where the prostate presented no tumor on rectal palpation could be best reached from above, while those in which the projection was low down could be operated on either through the perineum or above the pubes. The speaker said he believed, according to his personal experience, the Bottini operation certainly deserved a place in the surgery of the prostate, and he thought this fact had been proven by his statistics. The method should only be applied, however, to carefully selected cases. In a recent case in a man seventy years old, with frequent attacks of angina pectoris and edema of the lungs, it was considered unsafe to resort to either general or spinal anesthesia, and a Bottini operation was safely performed under local anesthesia.

Dr. Eugene Fuller, in the discussion, said he could recall two cases similar to the one reported by Dr. Meyer. In one a thick, finger-like projection of the prostate came from the upper part of the urethra and a second from below, coming together at the urethral outlet. On straining, these two masses would approximate and caused absolute retention. A calculus was found imbedded underneath the lower projection. In another case, a negro, there were three of these fleshy projecting masses, and in that instance there was a great deal of retention and phosphatic grit. In both of these cases very little prostatic enlargement could be felt through the rectum. In cases of this character, Dr. Fuller said, he thought that the suprapubic route was practically the only one that gave a chance to do thorough work. The speaker said he had done prostatectomy by the perineal method about 80 times and by the suprapublic method over 225 times. While the enlarged prostate could be removed in most instances through the perineum, the mere removal was not the only essential part of the operation. The condition of hemorrhage also had to be considered. When you had to deal with a flabby bladder, capable of holding, perhaps, a quart of blood, and without any expulsive force, in such a case, the speaker said he would not do a perineal operation, as he wished to be in a position to help such a bladder expel its contents. Under these conditions one was very apt to get passive bleeding and have trouble. He recalled such a case in which a serious hemorrhage occurred on the fifth day after the operation, and the man's life was undoubtedly saved by rapidly removing a blood-clot through the suprapubic opening.

Cystic Hydronephroma.—This was the theme of Dr. F. Kämmerer. The patient was a man, about fifty years old, who, when he was seventeen, had a severe attack of hematuria lasting two weeks. He recovered and remained perfectly well until about five or six years ago, when his present illnes began. He again had hematuria, which persisted for some time. Four years ago he entered the German Hospital, and while he was under observation there he passed no bloody urine for several months, but shortly after his discharge the attacks recurred, and peristed, with occasional intermissions. About a year ago he first noticed that his abdomen was increasing in size, and since then the bleeding has become more severe. Dr. Bierhoff made a cystoscopic examination, and established the fact that the blood issued from the left ureter.

When Dr. Kämmerer first saw the patient last June he had an immense tumor in the abdominal cavity. The entire abdomen was so tense that it was not easy to say whether it was cystic in character, as it afterward proved to be. The patient's general condition was very poor, and a blood examination showed that the hemoglobin was reduced to 40 per cent.

The usual incision for these large renal growths beginning at the spine and ending at the outer border of the rectus muscle of the affected side was made, and the peritoneum opened to determine exactly the position of the overlying colon. This was then easily pushed aside, in order to prevent any injury to the nutrient vessels of the intestines, which pass over the median surface of the kidney. It now became apparent that he had to deal with a cystic tumor connected with the left kidney. Very great difficulty was experienced in tearing away the firm adhesions of the tumor to the diaphragm. The tumor proved to be a hydronephroma, showing evidences of advanced cystic degeneration. The man made a slow but uneventful recovery from the operation.

Dr. R. Weil said that while the tumor resembled a hydronephrosis, the contents of the sac were entirely different from those met with in that condition. It was filled with a chocolate-brown fluid, Very little kidney tissue remained. The speaker said he had been able to find two exactly similar cases in the literature, and both gave the same clinical history.

Cancerous Prostate Removed by Suprapubic Incision.—This specimen was shown by Dr. Willy Meyer. The patient from whom the specimen was removed was a man of sixty years, who gave an old history of gonorrhea and syphilis. He was admitted to the hospital in the early part of March, 1904, and stated that his bladder symptoms dated back three months. He was at first unable to completely empty his bladder, and finally developed retention, so that it had to be drawn off with a catheter. He urinated about three or four times during the day, and the same number of times at night. When Dr. Meyer first saw him, a soft rubber catheter could pass without any special trouble, 150 c.c. of urine were passed, the residual urine amounted to 25 c.c. Rectal examination revealed an irregular, nodulated mass, which was so different from the usual forms of prostatic hypertrophy that, together with the cachexia and the short history, it raised the suspicion of malignancy. The cystoscopic picture also differed from the usual one of prostatic hypertrophy. The trabeculæ of the bladder wall, and the groove at the internal urethral orifice that were so characteristic of prostatic hypertrophy, were absent.

The patient was operated on May 21 of the pres-

ent year. Anterior to the bladder multiple glandular enlargements were found encroaching upon the bladder wall. After having opened the bladder, it was comparatively easy to introduce the fingers between the tumor and the rectum, and to remove the entire growth without injury to the latter organ. There was scarcely any hemorrhage. The infiltrated glands had invaded the bladder-wall to such an extent that permanent, water-tight drainage could not be instituted. The operation relieved the patient of the distressing constipation resulting from the pressure of the tumor. Death occurred in about seven weeks from pyelonephritis. Cancer of the prostate, Dr. Meyer said, was not a very rare condition, and probably often began within a benign adenoma. He emphasized the importance of early operative interference in these cases, before the growth had passed beyond the capsule. In later stages watertight suprapubic drainage, according to the Kaver-Gibson method, were the only means to ameliorate the patient's condition by a cutting operation.

Specimen of Chylous Hydrocele Fluid.—This was shown by Dr. F. Tilden Brown. The patient from whom this had been obtained was a man fifty-seven years old, a native of the West Indies, who had lived in New York for thirty years. Eighteen months ago a small stone had been removed from his bladder by litholapaxy. Following that operation, the patient complained of some pain in the left testicle, and subsequently it was noticed that the tunica vaginalis was gradually becoming distended. As there was some suspicion of syphilis—although the patient had never been treated for that disease—he was placed on potassium iodide in increasing doses. The treatment was continued for some time, but it had no effect on the scrotal tumor. The condition was then regarded as an epididymitis secondary to posturethral trauma, associated with a moderate hydrocele. An incision was made over the swelling, and upon introducing a trocar, pure milky fluid was withdrawn. Culture tests with this fluid had proven negative, and an examination of the patient's midnight blood had failed to show any *Filaria*. Under the microscope the fluid showed nothing but chyle. Dr. Brown asked to be informed if there was any other recognized cause for this condition beside the lymph vessel obstruction by the adult *Filaria Bancroftii*.

Dr. Fuller referred to a case in which a great many *Filaria* were found in the milky fluid.

The F. Tilden Brown Small-Sized Ureter-Cystoscope.—Dr. Brown also showed a No. 20 French ureter-cystoscope that he had had made specially for a child in whom it was necessary to catherize both ureters. It was made on the same line as his No. 24 French double ureter-cystoscope, but the smaller instrument took only the finest ureter catheters.

The Cystoscope as an Aid in Genito-Urinary Surgery.—By Dr. Follen Cabot. (Will appear in a subsequent issue of the Medical News.

Dr. F. M. Johnson, of Boston, Mass., said that the careful preparation of the patient, preliminary to cystoscopy, was of the utmost importance. He also advised testing the caliber of the urethra by the passage of a suitable sound before introducing the cystoscope. In order to illustrate the value of ureter-cystoscopy from a clinical standpoint, Dr. Johnson reported the case of a man who for four years had complained of almost constant pain in the region of the right kidney, from which he had been unable to get any relief, save through morphine. An examination of the urine showed that the case was apparently one of chronic catarrhal pyelonephritis, and upon introducing the cystoscope, clear, light-amber urine could be seen flowing from the orifice of the left ureter, while that from the opposite ureter was of a milky whiteness. The right ureter was catheterized, and the infected kidney treated by lavage. After four such treatments, the improvement was very marked. Microscopical findings in urine from right kidney showed a chronic nephritis probably of suppurative character. Another interesting case was that of an old soldier who had what was pronounced to be chronic and incurable Bright's disease. He complained of headache, indigestion frequent micturition and, at times, inability to walk. He had a stricture of the urethra, which was dilated; then both ureters were catheterized, and from an examination of the urine a diagnosis of chronic croupous nephritis was made. The treatment consisted of lavage of the ureters and bladder, and under this he improved rapidly. He gained ten or twelve pounds in weight, and while he was not cured, his more distressing symptoms had disappeared and he was able to return to work. Catherization and lavage of the ureters, Dr. Johnson said, if done slowly and gently, was devoid of much danger. The therapeutic value of this method, while still open to question, was well worthy of careful investigation and trial. He thought it advisable that the withdrawal of the catheter from the ureter should be accompanied by the introduction of a simple antiseptic remedial agent. In cases of chronic catarrhal pyelitis or catarrhal pyelonephritis from the irritation of an excess of urinary salts lavage of the ureters seemed to be very beneficial as an adjuvant to internal remedies. Dr. Johnson emphasized the importance of employing strict surgical precautions in doing uretercystoscopy. He had not found it necessary to use cocaine in the urethra, as gentle manipulation obviated its use. In the bladder, however, he preferred to use a one per cent. solution of cocaine, as the organ was then better able to retain the water that was put in before the operation was undertaken. Injections made into the kidney itself should be of about the same temperature as that of normal urine.

Dr. Fuller, in the discussion, said that while there was no doubt about the value of cystoscopy, some genito-urinary surgeons seemed to resort to the procedure as too much a matter of routine, while others neglected it too much. The preparation of the patient for the operation was very valuable, as the procedure became much simpler in a case where there was no tenesmus or straining, and where the urethra had become more tolerant. It was not always possible, however, to give much preliminary treatment, as many of these cases came from out of town and did not have much time. Dr. Fuller said he did not feel competent to express an opinion as to the value of medicating the pelvis of the kidney by means of catheterization of the ureters. As Dr. Johnson had said, however, the field was certainly worth investigating.

Dr. Frederic Bierhoff, in the discussion, said that while preliminary treatment for cystoscopy was not an absolute necessity, it was advisable in all cases in which it was possible to resort to it. By thorough disinfection of the parts, flushing of the bladder, and care in the use of instruments the chance of inflam-

matory reaction was greatly diminished, particularly if these patients would immediately take a hot sitz-bath on reaching home, and then go to bed. The use of moderate doses of quinine and urotropin still further diminished the tendency to reaction. One of the most important precautions was to thoroughly cleanse the cavity of the bladder and not introduce the cystoscope until the fluid returned absolutely clear. This procedure might in some cases take half an hour and prove very tedious, but the operator would be rewarded by the clearness of the picture he finally obtained. The quantity of fluid necessary to fill the bladder varied greatly between the male and the female bladder. The female bladder had a much greater capacity than that of the male, and in some cases it was necessary to inject as much as 450 or 500 c.c. of fluid. In the male, from 150 to 250 c.c. would usually be sufficient to distend the bladder and render all parts of it accessible. Too little attention, Dr. Bierhoff said, was usually paid to the light. He had never been able to adopt the so-called cold lamps, particularly in those cases where the bladder was filled with fluid. While this light looked bright enough outside the bladder, or in a bladder filled with air, it did not possess sufficient penetrative power in a bladder filled with fluid. The more brilliant the light the better were the chances to make a complete and satisfactory examination.

Dr. Bierhoff said that one of the more obscure but not infrequent conditions which we were able to recognize with the cystoscope was the bladder of tabetics. These bladders sometimes held a surprisingly large amount of residual urine. The speaker said he had seen the amount run up to 1,500 c.c. in a tabetic patient—after an attempt had been made by the patient to empty his bladder voluntarily—and this without any stricture or other cause. In some of these cases a well-marked trabecular bladder will be found, together with great dilatation, and the only explanation for this will be the spasmodic contraction of the compressor muscle. In all these cases of tabetic bladder, the cystitis was usually the first symptom that called the patient's attention to the bladder, and unless the physician kept this condition in mind, he was apt to be led astray. There were also numerous cases of bladder contraction which would escape recognition without the use of the cystoscope. The speaker said he recently reported a case of that kind in which marked vesical contraction occurred following the extension of a suppurative process from the testis to the cord and perforation of the abscess. The cystoscope was also of value in obscure cases of perirenal suppuration, in which there was a discharge of pus through the ureter.

Dr. F. Tilden Brown said he could substantiate Dr. Bierhoff's statement in regard to the presence of trabeculæ of the bladder independent of appreciable obstruction in the way of prostatic overgrowth or urethral stricture. The practice of using a large amount of fluid in the bladder, particularly the female bladder, was often a detriment rather than an advantage, because the bladder has a tendency when overweighted to fall backward and sag downward—pouching into the vagina. When this occurs the trigonum is in part or wholly below the level of the internal meatus, and then the ureters are quite inaccessible for catheterization. Dr. Brown said that the value of leaving the ureteral catheters in the ureters must be exceptional, and there were many disadvantages connected with such a procedure. The ureteral epithelium was very delicate and easily detached, and unless the greatest gentleness was exercised, the manipulations would give rise to more or less bleeding, and whether this is micro- or macroscopic a correct interpretation of the returns may be jeopardized. It was his practice to use short catheters in nearly all cases and pass them only 2½ inches, and to retain the cystoscope quietly in place while the eight to ten cubic centimeters collection of urine from each side was being caught.

Dr. Willy Meyer said he simply wished to emphasize the fact that the cystoscope had literally carried a bright light into the hitherto dark field of urinary surgery.

Dr. Winfield Ayres said that the true value of ureter-cystoscopy in its relation to the treatment of diseases of the kidney was still unknown, and opened a large field for investigation. If a catheter was left in an inflamed ureter for only fifteen or twenty minutes, it was apt to excite bleeding. In such a case the speaker said he would make his applications to the kidney as rapidly as possible, and then withdraw the catheter.

Dr. William K. Otis, in the discussion, said that the question of catheterization of the ureters had overshadowed the purpose for which the cystoscope was originally devised, viz., that of examination of the bladder. As a matter of fact, the instrument used for catheterization of the ureters was not suitable for examining the bladder, there being a strong tendency to diminish the caliber of the instrument at the expense of the optical apparatus, thus giving a small and badly illuminated field. The fundamental requisites for a good cystoscope being as large lenses as possible and as large a lamp as possible in order to give a clear, large and well illuminated picture. He himself was in the habit of employing cystoscopes of various sizes, using the largest possible in a given urethra, even as large as No. 30 F., thus obtaining a much clearer and more definite field than with the ordinary cystoscopes. As had been remarked by Dr. Bierhoff, as a preliminary measure to a successful cystoscopic examination it is exceedingly important to thoroughly cleanse the bladder, and the use of distilled water was preferable to ordinary sterilized water on account of the increased clearness of the medium.

Dr. A. V. Moschcowitz called attention to the value of uretercystoscopy in connection with cryoscopy. The freezing point of the urine from each ureter, as compared with the freezing point of the blood, would help to determine the functional capacity of the kidneys.

Drainage of a Prostatic Abscess Through the Ischiorectal Fossa. Dr. F. Tilden Brown, in the discussion on Dr. W. C. Lusk's paper, said that his experience with prostatic abscess was comparatively limited. He could only recall four or five cases, and in two of these the abscess had pursued the course which was not infrequently met with, namely, that of burrowing along the ischiorectal fossa and presenting besides the anus. The method of approaching these abscesses suggested by Dr. Lusk was a safe and comparatively easy one, and would obviate the possibility of rupture into the rectum or urethra. In some cases a urethral opening would perhaps be simpler and better.

Dr. Winfield Ayres said he had never yet met with a prostatic abscess that required opening; it had always ruptured spontaneously before he thought

it required opening. He recalled three cases that opened into the prostatic urethra, and in those the cure was exceedingly slow. In one of them three years had elapsed, and the cure was not yet complete. The other two persisted nine months or so. In one case the abscess ruptured into the rectum, and a cure was effected in less than a month. The only objection to the method proposed by Dr. Lusk was that the diagnosis was not always easy. If you made the diagnosis of an abscess deeply seated in the prostate and not close to the urethra, then it was safe to go in and open it; if, on the other hand, you made a mistake, and the abscess was located near the urethra, the relaxation of the pressure that would follow its incision would be apt to be followed by sloughing and the formation of an obstinate urethral fistula.

Dr. Edward L. Keyes, Jr., said he could only recall four cases of prostatic abscess, all dissimilar in character. In one there was a history of vesical suppuration, and a perineal section disclosed an old abscess cavity. In the second case there were several suppurating foci in the prostate, and in such a case, Dr. Keyes said, he did not think that the lateral incision suggested by Dr. Lusk would meet the requirements. This patient had an abscess pointing distinctly toward the rectum, and it was opened in that way. In this case there were two additional foci in the opposite side of the prostate, both of which opened into the urethra. This patient made a rapid recovery. The third case developed a prostatic abscess after an operation for vesical calculus. It opened into the rectum and the patient made a good recovery. In the fourth case there was a large abscess pointing toward the rectum. In opening this a perforation of the bladder wall occurred. The vesicorectal fistula closed spontaneously in six weeks without any further serious complications.

Dr. Francis Cruger Edgerton said that some months ago a man came into the Hudson Street Dispensary suffering from retention of urine. A catheter was passed, which caused a prostatic abscess to rupture into the urethra. Two or three days later he had a second attack of retention, and catheterization was again followed by rupture of the abscess. The retention again occurred, and he was finally sent to Bellevue, where the abscess ruptured for a third time. On the following day, Dr. Edgerton did a perineal section, and enlarged the opening into the urethra. The speaker said that in many of the cases he had seen, rupture into the urethra had occurred before the patients came under observation. If the method of dissection proposed by Dr. Lusk would be followed in those cases, it would be apt to result in a urethro-perineal fistula.

Dr. James Pedersen said that though the subject of prostatic abscess was generally regarded as one of minor importance, it involved many interesting points. Chief among these, he thought, was the difficulty in making a diagnosis, and therefore in deciding when to operate. He recalled four cases in which the presence of an abscess suddenly became apparent, though its presence had scarcely been suspected. On the other hand, he recalled two cases in which a well-marked abscess pointing toward the perineum had ruptured into the urethra while preparations for operation were being made. Both of these cases recovered without any complications.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

Section on Psychological Medicine.

(Continued from Page 912.)

Criminal Responsibility.—This was the title of an address by Dr. Charles Mercier, of London. On this subject he said there has been a difference of very long standing between the professions of law and medicine, a difference which he was sanguine enough to believe may be reconciled. The difference of opinion is largely due to the difference of aim, and there is little prospect of agreement until the object in view shall be the same for both parties to the dispute. It will be admitted that the legal mind approaches the question of criminal responsibility mainly and primarily with the object of protecting the community from wrongdoers; while the medical mind is apt to regard primarily, and perhaps too exclusively, the individual offender, and the justice or hardship of the punishment that is inflicted on him, and to strive for the mitigation of punishment in individual cases in which the law seems to bear with undue hardship on the criminal. The first thing to be done in order to reconcile the opponents is to show that these two objects are not necessarily antagonistic, but rather that they are two aspects of the same problem; that neither can be attained without the attainment of the other, that the complete solution of the problem would secure the attainment of both, and that the one suffers as much as the other from a faulty law, or from the faulty administration of a good law.

Moreover, he ventured to suggest that neither the protection of the community from wrong-doers, nor the protection of individual wrongdoers from excessive punishment, is the highest or the ultimate aim in dealing with criminals. Both of these, it seemed to him, are subsidiary to the attainment of a still more desirable end—the strengthening of the sense of responsibility throughout the whole community. This sense of responsibility suffers as much from an unduly severe as from an unduly negligent infliction of punishment. "Let us seek," he said, by way of illustration, "means by which we can so corrupt the conscience and debauch the mind of the man of passion who is trembling on the brink of crime, or of the man of feeble will who is tempted by circumstance, that he may deliberately cast the fear of punishment behind him, and say with eager choice, Evil! be thou my good! Could not we do so most effectually by addressing him thus? By saying to him, 'You are not as other men are. You belong to a separate class of human beings. You are marked off from the rest of your race from your birth, and are devoted and predestined to a life of crime. You are incapable of regulating your life according to the canons of rectitude: they do not apply to you. Your skull is oxycephalic; it is unsymmetrical; its frontal curve is less, and its parietal curve is greater than those of other men. Your forehead recedes; or, worse, it projects. Your chin projects; or, worse, it recedes. You have no wisdom teeth. Your ears are too large; they are too small; they are misshapen. Your hair is thick; your beard is thin. You are dark in complexion. You are unusually fair. You have a fixed look in your eye; you have a glassy stare; you look like a bird of prey; you have a singular air of *bonhomie*, you have an

angel face; you have the appearance of a wild beast: and the glance of a tiger; you have a peculiarly benevolent aspect. In addition to these stigmata, which mark you as a born criminal, you are shorter than the average; you are taller than most men. Moreover, you have tatoo marks on your arms, and perhaps on your body also. This being so, we regard you as irresponsible. You are a criminal, it is true: but the fault is not yours. It is not in the habit you have formed of yielding to your passions. It is not in your self-indulgence; your laziness; your slavery to impulse; your selfishness; your cultivated lack of self-control. No! It is impressed upon you by your inheritance. You, poor fellow, are visited with the sins of your father and grandfather, even unto the third and fourth generation of ancestry. You are a thief, a murderer, a violator, it is true: but this is not your fault. You are a criminal, as Falstaff was a coward, by instinct. In one word, you are a degenerate, and, since your crimes are no fault of yours, you shall not be punished for them. On the contrary, you shall be entertained, amused and instructed. You shall be treated with Turkish baths and massage, until your criminality departs from you. You shall exercise in a gymnasium, to the strains of a band of music, played by your fellow criminals. You are of weak mind; and therefore you shall be aesthetically cultured by a course of lectures on Chaucer, and Shakespeare, and Emerson, and Browning. You are a semi-imbecile; and therefore you shall be put through a course of Jowett's Plato. As a means of elevating your character, you shall be taught—journalism; and be provided with a newspaper to edit, whose contributors and readers shall be your fellow prisoners.'"

No, gentlemen, these are not the ravings of Bedlam; these are the teachings of the writers who call themselves criminologists, translated, out of a somewhat exuberant verbosity, into naked English.

Luxury for Criminals—Who Pays For It?—He then called the attention to the fact that these luxuries, by which the wicked man is to be turned away from his wickedness that he has committed, and made to do that which is lawful and right, do not grow spontaneously out of the ground; nor do they fall, like manna, from heaven. They are provided, for the use and delight of the criminal, by the thrift, the labor, the self-denial, of law-abiding men. If criminals and scoundrels of every order are to be thus pampered and coddled, what is to be done for the upright man, for the honest, self-restrained, law-abiding citizen, who sees, at the end of a lifetime of ill-rewarded toil and privation, borne with uncomplaining fortitude, no resting-place for his old age more luxurious than the workhouse—that workhouse which is scorned and derided by the occupants of these comfortable gaols. If the luxury of an Elmira, for instance, is not too good for the criminal, what degree of the splendor is good enough for the honest poor man, who, in the teeth of penury, has preserved his integrity? Even granting all that the fanatics of criminal pampering claim for the result of their methods—even granting that a certain small proportion of scoundrels may, by a course of Turkish baths, the lectures on English literature, and the study of Plato, be weaned, for a time at least, from a career of crime—is the game worth the candle? Is it fair, is it just to the taxpayer, often a poor man, and sometimes an honest man, that many hundreds, or it may be thousands of pounds of public money should be spent in turning a few criminals into indifferent citizens? There is joy in heaven, we are told, over one sinner that repenteth: but if the repentance were not to be secured save by an increase in the celestial income tax, it is fair to suppose that the joy would be but a mitigated and chastened felicity. But, apart from the unfairness of such a mode of treating the criminal, an even more important consequence of this doctrine of innate criminality, upon which the practice is founded, is the weakening of that sense of responsibility which it should be the aim of every system of criminal law to foster and strengthen. What will be the natural result of teaching an evildoer that his wickedness is the fault, not of his own vice, self-indulgence, dissipation and facility to temptation, but of the organization that he inherits from his ancestry? Will it not certainly be, that he will relinquish any struggles toward a better life that he may have begun, and will complacently pursue that course of crime that he is told is, for him, inevitable? A more pernicious and immoral doctrine it is difficult to imagine. For his part, he abhors and repudiates the doctrine with vehemence. Crime, as his friend Dr. Urquhart has said of drunkenness, is not a disease to be treated, but a vice to be punished. The more is it incumbent on us to see that the punishment is prompt, is certain, is apt, is adequate, and no more than adequate, to the offence. Of these elements in punishment, the majority must be left in other hands than ours. For its promptness, its certainty, its appropriateness, we must be content to trust the police, the judge and the prison authorities. The main question that we have come here to-day to discuss is, Who ought to be punished, and with how much punishment?

To the first question the answer—Wrongdoers, by which is meant, those who for their own gratification, and without justifying provocation, wilfully do harm to others. The whole gist of his argument lay in this definition; which has this advantage, that if it be accepted, it excludes from wrongness certain cases of doing harm, and provides the same criterion of responsibility, that is of liability to punishment, to both the sane and the insane.

Insanity and Responsibility.—Insanity may exonerate from punishment the man who injures another, but only by enabling him to satisfy the same condition that exonerates a sane person. In the insane as in the sane, the responsibility for guilt lies in the *animus nocendi*, or *scelerandi*. When their lordships said that "to establish a defence on the ground of insanity, it must be plearly proved that . . . the accused party was laboring under such a defect of reason . . . as not to know the nature and quality of the act he was doing," they were but saying that if from want of knowledge the *animus nocendi* was absent, the plea was established. It is true that their answer was not the general answer, that the *animus nocendi* is essential to guilt; but the particular answer, that, when this *animus* was absent from a particular cause, the prisoner is not guilty; but then it ought always to be remembered, though it never is remembered, that the judges were not asked the general question, "Under what circumstances does insanity in a criminal exonerate him from punishment," but the very restricted question, "What are the proper question to be submitted to the jury when a person afflicted with insane delusion respecting one or more subjects or persons is charged with the commission of crime, and insanity is set up as a defence?" The contention of his address was that the judges were right; that the *animus nocendi* is

essential to guilt, and that the constituents of this *animus* are contained in the definition: First, harm done, with no intention of obtaining gratification by the doing, is not wrong, and is not punishable. The difference between the salutary wound inflicted by the surgeon, and the malicious wound inflicted by the assassin, is in the respective intention of the actors, not in the consent or non-consent of the sufferer, nor in the result of the wounding. The surgeon may act without the consent of his patient, who may be unconscious from that fracture of the skull which the operator is about to trephine; yet the trephining is not wrong. Or the surgeon may do harm instead of good, and unwittingly hasten instead of retarding the fatal result of disease; still his act is not wrong, for he did not do the harm for his own gratification. But if he did the operation merely to display his skill, or to obtain practice in his art, he does wrong, even though by his operation he cures the patient. It matters not whether the intention is sane or insane; whether the skilled surgeon opens the cranium to excise a tumor, or whether a blundering madman splits the skull open to let out a headache; so long as there is no intention to gain gratification for himself by harming another, no wrong is done. Secondly, provocation or threat justifies retaliation in measure—in such measure as will prevent the threatened injury. One may stun, maim or even kill, him who is, in his firm and settled belief, about to kill him; and one's exoneration is complete, whether his belief is just and true; or whether it is a sane mistake; or whether it is an insane delusion. In either case, the *animus nocendi* is wanting. Thirdly, the harm must be done wilfully, or there is no wrong done, and therefore no wrongdoer to be punished. The law allows the principle. A prisoner is indicted, not for murder *simpliciter*, but for wilful murder. Wilful action implies and requires knowledge of the nature of the act, and of its obvious and natural consequences; and, further, implies and requires volition,—intention to do the act, and to cause, by so doing, the said consequences. If either the knowledge or the will is wanting, the act is not wilful; it is not wrong; it is not punishable.

Irresistible Impulses.—In his opinion, the doctrine of uncontrollable impulses has been invented to cover those cases in which crimes have been committed by persons who are plainly insane, but who cannot reasonably be said not to know the nature and quality and wrongness of their act; and the one doctrine has had to be stretched and distorted as much as the other in order to bring about the desired result. What has been intended when irresistible impulse has been pleaded, was not really irresistible impulse, but absence of will to do the deed—absence of that *animus nocendi* which is necessary to wrongdoing. Irresistible impulse, in the technical sense of a sudden outburst of maniacal violence, so rarely comes within the purview of a court of law, that, with a pretty extensive acquaintance with the subject, he was unable to cite a single case. The only case in which irresistible coercion of the will can properly be pleaded, is the case of obsession; and in this case, the act is not necessarily impulsive in the technical sense, although it must be regarded as irresistible. Obsession is a terrible malady. It is rightly regarded with suspicion and distrust by jurists, anxious to maintain the standard of individual responsibility; but of its existence there is not a shadow of a doubt, and in any given case, this existence is to be proved to the satisfaction of the Court by evidence given according to the ordinary rules. Doctors practising in insanity are, not seldom, consulted by persons, who complain, with the greatest distress, that they feel a horrible impulsion to do some act which is utterly abhorrent to them: to set fire, it may be, to their own property; to kill, it may be themselves, it may be those dearest to them. Against this impulsion they struggle with dismay and with horror. Sometimes they overcome it, and it fades away. Often they place themselves voluntarily under control in asylums to keep themselves out of temptation. Occasionally they apply to the police to be forcibly restrained. Sometimes they succumb, and the deed is done. In this last case, should they be punished? Such cases rarely, however, occur in criminal courts. Much more frequent are cases of another kind, in which, while knowledge of the wrongness of the act is present, the *animus nocendi* is absent, from want of will to do harm. For how many generations has the act of Virginius, in killing his daughter to save her from a fate worse than death, been applauded by the moral sense of mankind? How many times has it not been emulated by officers of our own army, whose womenfolk have been on the point of falling into the hands of savage foes? Cases in which children are killed by their parents, wives by their husbands, on a motive similar in character but insane, are very frequent in our courts. It was in such a case that that great judge, Lord Blackburn, finding that the prisoner could not be exonerated on the ground of not knowing that her act was wrong, told the jury that there were exceptional cases: a doctrine scarcely satisfactory if such cases were rare; but surely to be deprecated when they are very frequent. The application of the rule, that the *animus nocendi* is essential to guilt, would render it unnecessary to treat such cases as exceptional. The will and intention of the actors is, not to harm the victims, but to do them good. They are killed in order that they may be benefited. Of alternative evils, believed to threaten them, the less is chosen for them: and, the *animus nocendi* being absent, the actor, whether sane or insane, should not be punished.

The advantages of the course which he advocated, he said, were many. It introduces no new principle of law; it demands no legislation; it needs no definition of insanity; it does not disturb the famous answers of the judges; and it can be applied to every case, without stretching the principle, without straining or distorting the plain meaning of the language in which it is expressed. All that is needed is that the charge in the indictment should be proved or not proved; that when a prisoner is charged with wilful wrongdoing, he shall not be punished if the wrongdoing was not wilful.

The Legal Point of View.—Sir Herbert Stephen Burt said that, having read the abstract of Dr. Mercier's paper, he found himself in almost complete agreement with it. In illustration of what he, as a lawyer concerned in the administration of criminal law, conceived to be the principles there enunciated, he offered the following observations: I. The question whether or not there existed what was called a "criminal neurosis"—by which phrase he understood a set of peculiarities of bodily construction, which in concurrence were always or generally accompanied by a strong disposition to commit crimes—was a question not of law, but of medicine. All he had to say upon it was: (1) That, following the opinions he had heard expressed by Dr. Maudesley and Dr

Mercier, he did not believe it existed; (2) that if its existence were, in his judgment, proved, or decidedly probable, he should allow medical evidence to be given that a person accused of crime had a criminal neurosis, and should advise juries that this was evidence (strong or otherwise, according to circumstances) tending to prove the accused person to be guilty; (3) he should further regard the condition of criminal neurosis in convicted criminals as a reason for depriving them of their liberty to commit crimes for as long a period as seemed convenient, subject to their treatment being as little injurious to them as was consistent with public policy.

II. He believed that the point which it was essential to understand for the proper legal treatment of insane persons who committed crimes was that some criminals who were insane should nevertheless be treated as criminals—though it might frequently, or even usually, happen that their insanity should be considered a reason for mitigating the severity of their punishment. In explanation of this belief he offered a few remarks concerning cases of crime committed by persons suffering from insanity of different kinds, which ought to have—and in English law substantially did—lead to different results.

A. A case of which he had to do with several examples was that where a person suffering from some disease classed as epilepsy killed some one, generally a friend or lover, often in the presence of several persons, and almost always by cutting the throat. In these cases is appeared probable, as far as could be discovered, that the epileptic had no subsequent memory of the act of killing, or, in a minority of the cases, had only a faint and clouded memory like the memory of a dream. In these cases it seemed clear that only physical restraint (and probably very strong physical restraint) at the critical moment of the seizure would have prevented the killing; also that the act was unaccompanied by anything that could properly be called consciousness. It appears to him that those who did these more or less unconscious acts ought not to be punished therefor, but ought to be regarded as unfortunate instruments in a misfortune, as a man would usually be regarded who accidentally killed another by convulsive movements caused by a nightmare or a fit of delirium. He thought they ought to be treated merely medically, and should suffer no more restraint than was necessary as a precaution against a recurrence of the epileptic attack.

B. An example of a different class of acts of insane persons occurred in the constantly-recurring case where a woman—generally soon after pregnancy—killed her own child, oftener by drowning than in any other manner, but also not infrequently by cutting. In these cases, as well as could be discovered, she knew that she was killing the child, and meant to kill it, and did so because, being passionately fond of it, she had an obsession of mind sufficiently abnormal to be called insane, to the effect that death was highly desirable for the child. In these cases, as a rule, the woman could, when the mental obsession had passed off, remember what she had done, and deeply regretted having done it, but remembered also the thoughts which made her do it. He did not consider mere punishment suitable for such cases as these, but he thought there should, in any event, and irrespectively of the health of the sufferer, be a considerable period of enforced seclusion and submission to some form of discipline, because although the patient's knowledge of what she was doing, and of its general nature, was entirely overcome for the moment by the violence of her mental obsession it was never entirely suspended as in the cases in Class A. He judged this kind of mental obsession to be a thing against which the sufferer could and ought to have struggled, though the struggle in many cases might prove ineffective.

C. A third sort of case which came before the criminal courts rather less frequently than the two he had discussed was where the insane affection of the mind was a much more remote cause of the crime. Again, he took homicide as an example, because it was almost always in cases of homicide—and generally of murder—that these questions arise. In this class of case the patient, in consequence of a morbid affection of the mind, conceived a violent hostility towards some person who might be reasonably deserving of hostility to a considerable extent, or to a moderate extent, or not at all. The insane man, then, in gratification of his hostility, proceeded to murder his victim, employing for that purpose all the intellectual resources of the sane. He showed premeditation, care, resolution, and skill in arranging for his own escape. There was no reason to doubt that he knew as well as possible that he was committing murder, that murder was sinful, and a crime, and that he might be punished if he were caught. His immediate motive was hatred, and cruelty and treachery were probably features in his action, just as if he had been sane. The actual existence of all the provocation that he might conceive himself to have had would not in the least have affected either the immorality or the illegality of his act. He thought that insane criminals belonging to this class ought to be punished. He would treat them not as invalids unfortunately concerned in crime, but as criminals who happened to be suffering from a disease, which might or might not be a reason for mitigating the severity of their punishment. In some cases—though not very many—he thought the full penalty for the offence should follow the conviction, exactly as if the offender were perfectly sane. In others, where the extent of morbid delusion and insane behavior appeared to be comparatively great, he thought that conviction for crime should follow the offence, but that the punishment should be mitigated. He included in this class the cases where mental disorder amounting to insanity was the originating cause of criminal indulgence of the sexual passion, whether the resulting crime was murder or rape. He could not recall a case of an insane person tried for a crime of this character in which it did not appear that he knew perfectly well what he was about. He was inclined to think, after twenty-years' experience of the administration of criminal justice in England, that the above category of criminal acts committed by insane persons was practically exhaustive.

OPERATIVE TREATMENT OF RETROVERSION AND RETROFLEXION OF THE UTERUS.

BY WALTER A. JAYNE, M.D.,
OF DENVER, COL.

ASIDE from operations for the repair of injuries of the pelvic floor, which Emmet, that master of gynecologic plastic surgery, insisted were sufficient for the relief of retrodisplacements of the uterus, and which are accepted by all surgeons as an essential part of any procedure for their correction, all methods suggested for cases of retrodisplacements such as come to the operating table, are found on analysis to consist of either shortening of ligaments or creating new attachments. Omitting, for present purposes, these obviously necessary plastic operations and confining our review to those procedures designed to control directly the position of the uterus, we find that a few only have met with any general favor or merit serious attention.

Operations by the vaginal route are now reported and discussed so seldom as to leave the impression that whatever vogue they had at one time is now passed. The principles upon which they were based were never accepted as sound, and they received their support largely because of the avoidance of external scar, and the supposed greater safety in attacking the intraperitoneal disease complicating these displacements by the vaginal rather than by the suprapubic route. The difficulties in the performance of delicate and often complicated intraperitoneal operations through the vagina, guided largely by the sense of touch only, and the not infrequently resulting accidental injury of neighboring organs, deterred many operators; and when it became known that grave dystocia followed in very many of the cases becoming pregnant after the various operations of vaginal and vesical fixation, these procedures came to be regarded with positive disfavor except by a few. The therapeutic results of vaginal operations, including the shortening of the round ligament through the anterior fornix, did not appear to be any better than by other methods, and when the technic of abdominal operations had been so far improved that the suprapubic route, open to the eye, was demonstrated to be safer from operative accidents, and as safe or even safer from postoperative complications, the *raison d'être* of the vaginal route disappeared and apparently very few still practise these methods.

It has been frequently noted that the tissues of the upper layer of the pelvic diaphragm adjacent to the uterus are relaxed, permitting the cervix to drop, and favor a backward displacement. Laudable efforts have been made from time to time to correct this condition and maintain the cervix at a higher level by plastic operations; by creating adhesions in Douglas's cul-de-sac, or by shortening the uterosacral ligaments from above or through the vagina. These efforts have been more or less desultory, and the success following the methods pursued has not been so marked as to attract any general attention or inspire confidence. This pathological condition, though important at present, appears to be either not diagnosed or, when recognized, ignored by most operators. When a satisfactory technic for its correction is developed, the operation may easily prove a most important auxiliary to other procedures, even if it cannot be depended upon as a sole reliance.

The shortening of the round ligament through superficial incisions in the groins, commonly known as the Alexander operation (though others deserve much of the credit for it), performed after various methods in minor detail, has been under consideration and practised for twenty years. The acknowledged advantage of being an external operation, with no risk of peritoneal complications or to life; of utilizing normal ligament (and the strong fleshy part of it) to retain the uterus in position in a physiological manner, involving no interference with the normal progress of pregnancy and labor, combined with a high degree of efficiency, have caused its adoption by many operators for that limited class of cases for which it is applicable.

Objection is made to this operation that the round ligaments normally have little influence, if any, in preserving the anterior position of the uterus; that they are occasionally absent, are not easily found, and are often so slender as to break in withdrawal, necessitating other operation; that suppuration and sloughing are liable to render the procedure valueless; that hernia not infrequently results; that the operation is not an efficient cure and does not stand the supreme test of pregnancy, and finally, that the scars are an offense. Those who have gained sufficient familiarity with it to cope successfully with its acknowledged technical difficulties reply that while these objections are occasionally valid, unfortunate results as due to inexperience or accident and avoidable, rather than an essential defect of the operation in principle. They contend that the ligaments, if absent at all, as is questioned are in fact absent in so few cases, as to make that contingency not worthy of account, and that with care they should not break; that suppuration and sloughing are due to defective technic, too much dissection and bruising of tissue, or tying the

ligatures too tight; that hernias may be avoided by properly placing the sutures and closing the canal; that in practice the ligament is efficient in retaining the uterus, and relapses are uncommon, even after parturition; that the scars are small, insignificant, and scarcely noticeable after a few months, and finally, it is claimed, the records do not show a single case of complication of pregnancy or labor attributable to the operation. The successful Alexander would therefore appear to be an ideal operation for these uncomplicated cases during the child-bearing period.

Efforts have been made to extend the advantages of this operation to displacements complicated by the minor forms of disease of the appendages by dealing with them through the internal abdominal ring after enlarging it. A number of successful cases have been reported, but the suggestion is too recent to permit of a judgment upon its relative value or the possibility of safeguarding against hernia.

When these displacements are complicated by conditions requiring abdominal section, it is the accepted opinion that some intra-abdominal method should be selected for their relief; and the choice lies between some operation upon the normal ligaments or creating a new attachment of the uterus.

Those who believe in the desirability of using the round ligament for holding the uterus forward have endeavored to make it efficient by folding and shortening, or by creating a new attachment between it and the anterior abdominal wall, or to the uterus, anteriorly or posteriorly, and incidentally shortening it. Some of these operations have been performed over a period covering a number of years and have been regarded as fairly efficient; yet, looking back, it would appear that even those procedures regarded with the most favor have been utilized largely as a makeshift to avoid the attachment of the uterus to the anterior abdominal wall, rather than because of the confidence felt in the method, either as originally proposed or as modified from time to time. All these intra-abdominal operations on the round ligament, in common with the external shortening of these ligaments, already mentioned, have the advantage of not interfering with the normal progress of pregnancy and labor. With one or two exceptions, to be mentioned later, these operations have depended for their permanency and success upon the slender, weaker part of the ligament as it passes through the inguinal canal rather than upon the fleshy, stronger, intra-abdominal portion, and upon the continued integrity of adventitious tissue, the adhesions between the folds of the ligament or at its new attachment, usualy peritoneal. These facts, in the absence of satisfactory reports of final results, have caused distrust of the real and permanent value of these operations, however successful the primary result, and a suspicion exists that relapses are common. For these reasons many who preferred the use of the round ligament in principle have, in the absence of a procedure which could be regarded as sound and reliable, accepted and practised the attachment of the uterus to the anterior abdominal wall as offering the best solution of the problem.

For others, suturing the fundus of the uterus to the anterior abdominal wall has been the operation of choice, and being simple in performance, efficient, and withal so quickly done as not to prolong a section materially, even when accompanied by shock, it has deservedly been held in the greatest favor by the majority of surgeons; and by many it has been used for those simple, uncomplicated cases not otherwise calling for section, and for which the operations of the Alexander type have been held to be particularly applicable.

The firm attachment of ventral fixation, as first practised, was soon found to interfere seriously with the normal development of the uterus during subsequent pregnancies, inducing various complications, among them abortion and dystocia in a very considerable proportion of cases. To avoid these complications, the slighter peritoneal adhesion of suspension of the uterus has been substitued, except possibly for patients approaching or past the menopause, without expectation of future pregnancy, or those physically sterile. It is urged that the adhesion, however slight, is an abnormal one, and occasionally gives rise to more or less annoying symptoms or grave complications. Reports go to show that even in the hands of competent men, with every care in technic, its character cannot always be so limited as to insure a sufficient mobility of the uterus to admit of its full physiological development during gestation and avoidance of complications in labor. The connecting band is of adventitious tissue, and while, if slender, it may easily stretch during pregnancy, it is admitted that it cannot be depended upon after labor to undergo coincident involution to such an extent as to be again efficient and insure against relapse. The operation is popular, and for years it has been the one most commonly applied in abdominal cases. Its advocates direct attention to the very large number of cases showing no untoward symptoms, yet the fact remains that cases are occasionally reported in which unfortunate results have followed, demonstrating that the disadvantages above mentioned are positive in a certain, though possibly small number of instances, and at least are not so significant as to be ignored. The autoplastic operation, with the use of peritoneal membrane to retain the uterus, has been tried, but with what relative value is not yet clear.

Whatever opinion may ultimately be held regarding the relative value of shortening the round ligaments in the groins and suspension of the uterus for cases of uncomplicated retrodisplacements, the value and efficiency of the fleshy inner portion of the ligament, as utilized in the Alexander operation, appears to be generally rec-

ognized, and attempts are being made to extend its use. Methods have quite recently been proposed of attaching a loop of the intra-abdominal portion of these ligaments to the anterior abdominal wall more firmly than by the peritoneal adhesions formerly depended upon, by threading a loop through a small wound in the peritoneum, muscle and fascia on either side of the median abdominal incision, and fixing it by suture, thus suspending the uterus by the strongest portion of the ligaments and imitating as nearly as possible in intra-abdominal work the result following the Alexander. Should experience show operations of this type to be free from postoperative objections and quickly performed, they may offer a ready means of correcting these displacements in cases in which abdominal section is required in a safer, more physiological and efficient manner than heretofore suggested, and go far toward giving a satisfactory substitute for attachment of the fundus to the anterior abdominal wall, especially for women in the childbearing period of life.

STONE IN THE KIDNEY; ITS DIAGNOSIS AND OPERATIVE TREATMENT.[1]

BY JOSEPH RANSOHOFF, M.D., F.R.C.S. (ENG.),
OF CINCINNATI, OHIO.

Twenty-five years ago a formal operation for stone in the kidney was unknown. Since Morris recorded his first case, a little over twenty years ago, the entire subject of nephrolithiasis has been so thoroughly developed that in any single paper of conventional length only a few points of special interest can be touched upon.

I intend, therefore, to beg your attention to the consideration of certain phases of diagnosis and indications for operative treatment. With the rapid strides that have been made in our diagnostic methods of studying the kidney, few cases are now operated upon for stone with a negative result. Nevertheless, the elating thrill which the surgeon expects to experience, when the finger touches the stone in the opened kidney, is not always felt. In its place is chagrin if not discomfiture, when the fullest search fails to reveal the object sought for. To whom has it not occurred? A few years ago the writer saw one of the foremost specialists in kidney surgery fail to find a stone in two cases within ten days. That a kidney may harbor a stone without giving rise to symptoms is now and then shown in the mortuary. A stone, even of large size, may be carried about for many years and led to destruction of the kidney by suppuration, and still give no sign of its presence.

I beg to present this stone, weighing over one ounce, removed, with the kidney, from a man of twenty-one years, four years ago. With the exception of one day spent in bed after an injury sustained while playing baseball, the patient had never known a day's illness. A large lumbar abscess formed and opened spontaneously while the patient was walking about. The sudden discharge was the first intimation that he had of anything wrong. He sought relief from the annoying fistula in the loin. Until his attention was called to the almost milky appearance of his urine, he did not know that anything was wrong about it. Similar cases have been recorded, but they certainly are very rare.

Until the technic of radiography was brought to its nearly perfected state, every surgeon who often operated on the kidney met with occasional disappointments. Even to-day, as has already been intimated, errors in diagnosis will occasianally be incurred. Two questions, necessarily correlated, at once arise, the solution of which would remove the obloquy attending a seemingly fruitless if not hazardous operation. They are: First: Have we any positive and absolute method of recognizing stone in the kidney? And second: Are there any other pathological conditions in the kidney, the symptoms-complex of which cover to a nicety that of stone? In every case of suspected stone, the symptoms should be studied, and perhaps a presumptive diagnosis made before resort to radiography is made.

In a broad way the symptoms may be divided into two great groups: (1) Those due to the supposed passage of the stone through the ureter,—the renal colic proper; and (2) those due to processes constantly at work in the kidney because of its containing a stone, a condition of chronic nephrolithiasis.

As an element of diagnosis, the kidney colic *per se* is largely overrated. In a very large number of cases of kidney stone there is no renal colic from beginning to end. It is supposed to depend upon the passage of a stone through the ureter. Many times the corpus delictum is voided in the natural way. These are the cases that do not ordinarily require surgical intervention. When it is remembered that many stones are fixed in the kidney, that only comparatively small stones can get into the ureter, and that smooth bodies like the ureteral catheter are tolerated for long periods without inducing pain, it must at once become evident that for many cases we must seek another explanation of so-called renal colic than the spasmodic contraction of the ureter.

A small stone comes into the bladder from the kidney, becoming the nucleus of a large stone or is voided without having ever produced a renal colic. That sharp or irregular stones in their passage produce pain there can be no question, but the explanation of the pain must be sought in the occlusion of the ureter, usually the upper part of its course, and the consequent increase of the tension of all the structures contained within the kidney capsule proper. A tumor of the kidney suddenly growing into the pelvis, the entrance of a mass of tuberculous detritus into the upper ureteral orifice, a twist of the ureter or a movable kidney, may each produce symptoms

[1] Address delivered before the Kansas City Medical Society.

which cannot be distinguished from those usually ascribed to the passing of a stone. Furthermore, increased intracapsular tension without obstruction of the outflow from the pelvis will often produce pains closely simulating renal colic. Very acute congestions of the kidney with hemorrhage into the parenchyma, acute exacerbations of the tuberculous processes, and, above all, acute venous congestions in chronic nephritis, not infrequently limited to one kidney, may give rise to pains that might be classed with renal colic. That a renal colic may be simulated by a temporarily impacted gall-stone is of general knowledge. Even with a successful skiagram showing a stone, the differential diagnosis is at times impossible.

Dr. Barnett (*Annals of Surgery*, vol. 37, page 36), well illustrates a case of this kind. Every surgeon has been called upon to do an interval appendectomy in the presence of a kidney stone. In the latter condition there is very often great tenderness over the crossing point of the ureter and the pelvic brim, and in cases of appendicitis developing toward the pelvis I have even seen such strangury as is usually associated with urinary disease. Morgagni already recognized the fact that inflammatory conditions of the kidney cause symptoms which closely resemble those of disease of the bladder. Rovsing remarks that since he has used the cystoscope, his cases of cystitis have been reduced 50 per cent.

Our more positive methods of recognizing stone should not lessen our attention to the urine. A careful investigation of quantity, composition and search for the presence of formed elements continued for weeks will rarely fail to point to or from the kidney as the site of the lesion.

With the close of the colic, or in its absence, there comes up for consideration the second, and, in my judgment, the more important symptom group, that of chronic nephrolithiasis. When the stone is firmly fixed in the kidney and away from the pelvis and the ureter, we may have to depend on it entirely. Pain, spontaneous or elicited by pressure, changes in the urine and the frequency of its expulsion are the general symptoms indicative of progressive aseptic changes in the kidney before it has come to palpable enlargement. While not one of them is in any sense pathognomonic, their grouping is such that a correct diagnosis can generally be arrived at. Of greater diagnostic import than spontaneous pain is that elicited by pressure. Bimanual examination, the patient lying on the sound side, will cause a sharp pain in the region of the kidney, or the course of the ureter, when the patient takes a very deep inspiration. Tapping the kidney after the manner of Mr. Lloyd, is an excellent adjuvant. For purposes of comparison, I have long been in the habit of examining my patient, while he stoops over before me resting his hands on a chair. With the extended fingers placed over the lateral costo-iliac interval, I make simultaneous and equal pressure with my thumbs along the lower borders of the last ribs from end to end. I know of no way in which pressure tenderness due to a stone can be better elicited. It is far more acute than that caused in the first stages of tuberculosis and renal tumors.

The urine in chronic nephrolithiasis presents abnormal elements which afford perhaps the most valuable single guide to diagnosis. I allude to the persistent presence of microscopic hematuria. Almost every specimen examined during a period of months will contain from one to twenty red cells in the field. If not easily found in one or two examinations, violent exercise will produce microscopical bleeding. This feature is of special importance, since the urine to the naked eye is seemingly normal. Even under the microscope the blood cells are often detected with difficulty, because of their decolorization; often they are little more than shadows. In a paper read eleven years ago, I directed attention to this important point in the diagnosis of kidney stone, and my experience since has emphasized its value. By itself it is the most valuable sign of nephrolithiasis. In this connection the relative number of white cells is important, since in aseptic nephrolithiasis they are few, whereas in the tubercular they are always numerous. Until pyelitis has developed, the preponderance of the red cells over the leucocytes, as found in the urine, is like that of normal blood.

Crystals in the urine, as indicative of stone and of its composition, are of very little diagnostic value. To be of any value at all the crystals must be found in the urine immediately after it is voided.

Except when a stone is in process of growth, crystals can hardly be expected. In fact, the patient with kidney stone rarely gives the history of having passed sand with his urine. In several of my cases very accurate examinations were made over protracted periods with negative results. In connection with urinalysis it is, of course, essential to determine the quantity and the presence of albumin. Likewise is it important to make a rigid search for casts, for in many cases where operations have been performed with negative results chronic nephritis with acute hyperemias have been found, at times unilateral, as already indicated above.

The temperature chart in nephrolithiasis is of secondary importance. In a few of my cases the colic itself was associated with fever and that without suppurative infection. As in cases of common duct, stones without suppuration in the duct or the gall-bladder, elevations of temperature occur, so it is in impaction of a renal calculus. In the chronic state of nephrolithiasis, on the other hand, slight elevations of temperature continued through a long period and with a distinct tendency to recur irrespective of any renal colic, are a most important element in the diagnosis. How these septic changes in the kidney occur about a stone is fairly well known. It does

not necessarily mean a pyelonephrosis with enlargement of the kidney sufficient to make it easily detectable. Even when dislocated into the wound for the removal of a stone, such a kidney with pyelitis and slight distention of the pelvis may not seem notably enlarged. When the kidney is greatly enlarged and has become converted into a pus sac, the diagnosis of stone is of secondary importance. All cases of pyonephrosis with sacculation present practically the same symptoms with the exception of those in which tuberculosis is the underlying factor.

Given the diagnosis of renal calculus, it is perhaps possible to differentiate parenchymal stones from those in the pelvis, but it is not possible to differentiate the latter from stones in the ureter. The X-ray has shown that perhaps 20 per cent. of stones are in the ureter, all of the symptoms indicating a higher site. This must account in part for the frequency with which stones were not found before radiography was used. In one of my earlier cases a most careful search of the kidney by splitting it failed to reveal a stone. Nine weeks after the operation, the patient passed a small ureteral calculus and was relieved of his symptoms.

The newer methods of cystoscopic, ureteral examination and separation of the urines, is of less significance in the therapy of kidney stone than in other surgical affections of the kidney requiring operation, since nephrectomy practically is never justified as a first operation for kidney stone. The cystoscope gives us invaluable data in determining in the first place that the bladder is free of primary disease, and frequently it shows us by an abnormal condition of the ureteral opening which kidney harbors a stone. The use of a wax-tipped ureteral bougie, as suggested by Kelly, will occasionally give a positive result, but it is a chance on which little reliance can be placed. Albers-Schönberg has shown in a number of cases that the ureter would permit a catheter to pass, although it contained one or more stones. Bierhoff has recently suggested filling the renal pelvis with a solution of boracic acid, which displaces a stone if present. The procedure is followed by a slight hematuria, which he considered positive. He cites four cases.

How perfectly a positive result by radiography displays a stone in the kidney, I beg to show by a number of plates. Although subject to occasional errors, a radiographic presentment is with our nearly completed technic a *sine qua non* for a positive diagnosis. Kümmel and Rumpel reported a series of 18 cases positively recognized in this way, and each one contained a stone. Joseph F. Smith was enabled to recognize a stone 13 times with success. Leonard, as is well known, in a report of 300 cases, found stones in 36, of which 50 per cent. were in the ureter. In five of ten cases operated upon no stone was found. That ossification of an abnormal rib cartilage or the presence of a phlebolith may simulate a stone in the plate, there can be no question. When one considers the small size of the many kidney stones and the depth at which they are placed in many fat subjects, it is difficult to conceive how the X-ray can invariably portray the presence of a stone. Perhaps in every case a negative result after repeated attempts allows the exclusion of a calculus, to quote from Kümmel and Rumpel. A single negative result is not conclusive. With the improved technic, stones, no matter what their composition, will cast a shadow. That the interpretation of this is sometimes erroneous, a plate of one of my recent cases shows very well. The patient had passed a number of small stones during the year. The picture showed four rather large stones. The operation revealed 20 stones, all of which could have passed except two. They were so closely packed together in the pelvis, that they appeared as four stones.

In considering the operative treatment of stone in the kidney, it must first be predicted that the really brilliant results achieved in this field have not impressed the profession at large with that confidence in the operation which, for example, belongs to operation on the gall-bladder. The reason for this doubtless is that before more exact methods were resorted to, negative findings were very frequent. Ten years ago I collected 44 cases of this kind. Doubtless the number could easily be trebled to-day. I have myself operated six times with negative results. In one case, indeed, the kidney was explored twice. The failure to find a stone where the diagnosis is made is now a very unusual thing. It is noteworthy in this regard, however, that I could find in the literature no cases in which death followed the exploration of the kidney for a stone. In many the operation leads to the discovery of conditions simulating stone which are remediable by operation. Among surgeons therefore, it is becoming an axiom that the presence of a renal calculus is an indication for operation. Although it is usually attended with less suffering than stone in the bladder, it is fraught with infinitely greater danger to life.

The development of pyelitis, or of pyonephrosis, or in the absence of a septic infection, the production of a chronic interstitial nephritis with atrophy of the pyramids and great thickening of the capsule proper of the kidney are sufficient indications for operation. When one has seen many cases of kidney stone, one can almost tell from the appearance of the capsule when the kidney is exposed, and the induration of the perirenal fat, whether or not a stone will be found within. Literature teems with cases, in evidence of the great danger which the subject of kidney stone runs from the sudden onset of calculous anuria.

Calculous anuria is, of course, an absolute indication for operation. Although in rare cases such anuria may last six to eleven days before ending in death, operation ought not be delayed for more than twenty-four hours. The anuria

must cause degenerative changes in the renal epithelium which may make the resumption of normal function difficult or impossible. Statistics show conclusively that in proportion to the time of interference the mortality of operation is low or high. The question as to the kidney to be operated upon is usually solved aright after considering the side of the last renal pains, the tenderness, etc. Unfortunately in those cases where it would be most needed, the aid from cystoscopic examination and radiography cannot be obtained. It is better in these cases to open the wrong kidney than not to operate at all. For the reflex anuria may in this way be relieved as has been shown in a number of cases. The cases in which operation is not indicated are those in which the patient from time to time after a severe colic passes a small stone. I beg here to present a number of stones, of which the patient had been passing many hundreds during a period of seven years. The patient is now seventy years of age, and for a year and a half has passed no stones. A remarkable feature of this case is that the stones, when passed, look rather as though a successful crushing operation had been done. Just what produces fracture of these stones in the bladder is something I have been entirely unable to find out.

In regard to nephrolithotomy, it may justly be said that no other major operation presents so low a mortality. Morris reported 34 aseptic operations with one death. Tuffier reported eight cases without a death. Of my 23 cases there was one death, due to intestinal obstruction from tight packing and pressure on the nerves to the colon. Israel reported a similar case. According to Rovsing there is a mortality of seven out of 115 cases. How much the graver operative interference in septic cases is shown by Morris, who lost 10 out of 43 nephrotomies and five out of 17 nephrectomies.

As regards the operation itself, the choice between incision of the kidney and incision of the pelvis, has, I think, been definitely settled in favor of section of the kidney. The ease with which wounds of the renal parenchyma heal, the extent to which the kidney can be incised for exploration and for removal of large stones and the greater danger of severe hemorrhage and of fistulæ remaining, where the pelvis is incised, have led surgeons to choose the incision through the kidney substance as the normal procedure in nephrolithotomy.

The operation is easy or difficult in proportion to the facility with which the kidney can be delivered into the wound. Where the shortness of the pedicle or extrapelvic adhesions interfere with the delivery of the kidney, the operation becomes difficult in the extreme. Surgeons choose the longitudinal, convex, marginal incision recommended by Giron in 1856. It is safe because the vascular anastomosis between the anterior and posterior halves of the kidney is by no large vessels. This line of safety which Kelly has recently proposed to call "Brödel's line" was previously described from corrosion preparations by Hyrtl in 1869. In none of my cases where this incision was done was the hemorrhage other than parenchymatous. I never have used a ligature within the kidney. To reduce this hemorrhage even to a minimum, the incision should as a rule not be longer than is needful for the introduction of the exploring finger. This makes the hemorrhage nil, while the search for the stone progresses. A short incision over the upper pole and another over the lower pole permits the examination with the finger of both the upper and the lower and the common pelvis, and permits us to reserve the so-called post-mortem section of the kidney for cases in which the finding of a stone is very difficult. Hemorrhage is easily controlled by the fingers of an assistant or by throwing a temporary rubber ligature around the pedicle. The objection to this method lies in the ease with which, by the manipulation necessary to accomplish it, a small stone might be pushed from the pelvis into the ureter, and the difficulty of sounding the ureter while the ligature is in place.

Retrograde catherization of the ureter must be considered essential to every operation for stone in the kidney. Even if a stone is not found in the ureter, a stricture, a valve or kink may be detected and relieved.

That the exploration of the ureter sometimes necessitates a very large wound has for many years impelled me in almost all of my kidney work to make the long, oblique lumbo-abdominal incision, from which by extension downward and inward the ureter can be exposed as far as may be necessary. In all aseptic cases the suture of the kidney is made to follow the removal of the stone. Immediate closure of the wound by suture is justifiable even in marked cases of pyelitis, if the ureter is competent to act as a natural drain. An exception in regard to immediate suture of the kidney must be made in those cases of aseptic nephrolithotomy in which anuria compelled the operation. In these cases it is doubtless safer to drain temporarily. When the kidney is enlarged and sacculated drainage is, of course, to be adopted. Nephrotomy for calculus pyelitis and pyohephrosis has a mortality of 21 per cent.

In view of the well-known frequency with which the second kidney is involved in calculus pyelitis, operative interference in this condition should be limited to incision, drainage and perhaps, in bad cases, to nephrotosis. It is remarkable how when a sacculated kidney is split in these cases and its margins stitched to the wound edges, and shrinking of the sacculation is established, the kidney gradually resumes a form something like the normal. Because of the completeness of the drainage, nephrostomy thus performed has a signal advantage over the older method of drainage.

Primary nephrectomy, as indicated, should never be performed for stone, except, as has occurred in the hands of Israel, when the hemor-

rhage is uncontrollable. Neither the branched form nor the size of the stone should weigh against conservatism. Stones weighing two ounces and more have repeatedly been removed and the kidney saved. Rovsing has recently reported the removal of one weighing five ounces, a fistula remaining for only a short time. It is in these cases of very large stones that profuseness of hemorrhage has necessitated immediate nephrectomy.

In conclusion, I beg to call attention to those cases in which the search for stone is negative. We cannot deny that there are other pathological conditions of the kidney, the symptom complex of which cover to a nicety that of stone. An analysis of them enriches our knowledge of renal pathalogy by two important data. They are: First, that chronic interstitial parenchymatous and capsular inflammation of the kidney may be limited to one side. Rayer already called attention to a case of this kind in his classical treatise on the kidney. Carefully studied cases of this kind are not numerous. I presented one with a section of the kidney before the Southern Surgical Association three years ago. The patient remains entirely well. Second. It is of prime importance that a surgeon should not consider an operation on the kidney in which he expects to find a stone negative in its results when changes in the kidney are found which, as in the case reported, cover to a nicety the symptoms of stones. Capsule splitting and the section of the kidney will doubtless relieve many cases which simulate stone, and which because of the impossibility of making positive diagnosis are not now subjected to an exploratory operation.

In conclusion, I would advise that in every case operated on with a result negative as to the finding of a stone, a small section of the kidney be removed for microscopical examination. It is only in such a way that minute changes of the kidney can be discerned, changes which, although seemingly slight, are often capable of producing, as in a number of cases reported, symptoms of great severity.

THERAPEUTIC VALUE OF COLORADO CLIMATE.

BY F. GILLETT BYLES, A.M., M.D.,
OF DENVER, COL.

In these days of growing distrust in the all-curative power of drugs, increased attention is being given to the subject of hygiene and sanitation, as a means of prevention of disease, and an increased interest in physiological therapeutics as a means of treatment.

Being a resident of Colorado and in frequent contact with people who are sent here from the Eastern States, on account of ill health, I am impressed with the character of cases who come here expecting immediate recovery, and more impressed by the advice given many of them by their home physicians. Judging from the number of cases of tuberculosis, which are sent here in the last stages of the disease, or with a constant high temperature and are left to spend their few remaining days among strangers, without the comforts of home and often without either money or friends, we are led to believe there must be a mistaken idea among many physicians as to the class of cases that are likely to be benefited and the class that are made worse by our Colorado climate.

The hope of being able to suggest something on this subject which has been forcibly impressed upon me, since coming from Pennsylvania to Colorado, is the excuse for this paper.

The intelligent selection of cases to be improved by our elevated climate is probably best attained by a brief resume of the physiological effects of altitude.

Climates may be classified as either sedative or stimulating. Jacksonville or St. Augustine, Fla., or Biloxi or Bay St. Louis on the Gulf, are instances of health resorts in a sedative climate.

The climate of Colorado, on account of its elevation, is classed as a stimulating climate.

The principal atmospheric differences observed in moving to locations of greater altitude are lessened atmospheric pressure, lowered temperature and lessened humdity. The most important physiological effects caused by lessoned atmospheric pressure are a quickening of the pulse—about one or two beats for every 1,000 feet of elevation—and a quickened and deepened respiration.

Many persons in ascending Pike's Peak, which is 14,143 feet high, suffer with what is known as "mountain sickness." This is manifested chiefly by very rapid and irregular heart action, accompanied by a sense of suffocation and extreme shortness of breath greatly aggravated by muscular exertion.

It consists essentially in the inability of the person to breathe in enough oxygen, not that there is not enough in the atmosphere for his needs, but because, on account of the lessened pressure, he is not able to use properly what there is. We know that the quantity of oxygen per cubic foot lessens as the density of the atmosphere, but it has been shown that a man does not feel any inconvenience from lack of oxygen until the per cent., which is normally about 20.96, has fallen to less than 13.7

This distress caused by lessened pressure induces our natural forces to work out a means of compensation. This compensation is brought about in two ways. First, the individual learns to expand more fully every part of his lungs, his breathing is more rapid and also a great deal deeper and fuller. His chest measurements increase usually from one to two inches. Second, the oxygen carrying power of his blood is increased by an increased amount of hemoglobin, and also by an increase in the number of red blood corpuscles.

This condition, which enables the man to breathe easily, will be accomplished in from three days to two weeks, and will continue as long as

he remains at this altitude, returning to its former state upon his descending to a lower level.

This effect of lessened atmospheric pressure, which is very marked at places of great elevation, as on the mountain peaks, is, to a greater or less extent, effective at all places of less elevation, and the means which nature uses to bring about a compensation constitute one of the important means of cure to patients submitted to its influence. With this idea in mind we could, I think, easily predict what cases of lung disease would be benefited by a change to a greater altitude.

It is reasonable to suppose that the increased circulation and increased exercise of the lung caused by altitude, would add vigor to the lungs of one who inherited a tuberculous tendency or, if the altitude is not extreme, would be useful to one suffering from incipient tuberculosis, especially if of the more chronic form.

It is equally evident that cases of acute phthisis or those far advanced in the disease, would be made worse by the change. That such deductions are correct is proven by the experience of the profession in Colorado.

The air is cooler in Colorado than in places of the same latitude and less elevation. Generally speaking, the temperature of the air falls one degree F. for every 300 feet elevation.

Cool air is stimulating to the nervous system, also to respiration and digestion, and indirectly to appetite and assimilation with the attendant gain in weight and strength. Heat has the opposite effect. Cool air is almost always dry, at least the cooler the air the less moisture it can contain. In addition to the influences of the temperature on humidity, the great distance of Colorado from any large body of water, its sandy soil and other natural causes render the atmosphere very dry. The actual annual precipitation of Pittsburg is 3½ times that of Denver. The lessened humidity of our atmosphere has a marked effect on many forms of disease. There can be no doubt that a lack of moisture inhibits the growth of many of the disease-producing bacteria. Tubercle bacilli thrive best in a warm moist atmosphere, and their growth and development are undoubtedly retarded by the opposite conditions.

Excessive secretions of the nasal and bronchial membranes are checked by the constant inhalation of cool, dry air, and the diseased condition causing them is often thus remedied. Furthermore, the lessened humidity of the air has a great influence on our sunshine, not only in its amount but also in its effect on the comfort and health of the people.

There are fewer clouds and more bright days in Colorado than in the East. Denver has 42 clear days to every 27 clear days in Pittsburg. This enables health-seekers to spend most of their time out of doors, and the mild winters along the eastern slope of the Rockies make it possible for one to spend most of his waking hours and all of his sleeping hours, throughout the year, outside of stuffy ill-ventilated rooms. The greedy manner with which the dry air goes for water favors evaporation of perspiration.

This not only adds greatly to our comfort in summer, but lessens the depressing effects of heat. There are no sultry days here and no cases of heat prostration. There being little moisture in the air, the sun's rays pass through more directly. The heat of the ray is not absorbed by intervening moisture, and, on this account, the difference of temperature in the sunshine and the shade and during the day and the night—diathermancy—is greater here than at places of less altitude. The diathermancy increases about one degree for every 250 feet of elevation.

On account of the directness of the sun's rays, their therapeutic power is increased. The great abundance of light has, doubtless, an important influence on physical and mental conditions of invalids, and the germicidal influences of the actinic rays is doubtless greatly increased by elevation and lessened humidity. The greater freedom of the mountain air from micro-organisms and the rapid action of light on photographic plates, as well as the brilliant tints of mountain flowers, all indicate either a greater abundance or a greater potency of the violet and ultraviolet rays. In my opinion phototherapy is of no inconsiderable importance in bringing about the cures of Colorado.

I believe that it is an established fact that the per cent. of deaths from tuberculosis, in any locality, is indirectly as the altitude of the locality (omitting, of course, the cases contracted elsewhere). It is safe to say that the cases of this "great white plague" contracted above 6,000 feet, are very rare indeed.

Other things to be taken into consideration in the selection of a suitable climate for a sick person are, character of the soil, freedom from disagreeable winds, character and purity of drinking water, as well as hotel accommodations and opportunities for earning a living. In all these respects Colorado affords unequaled advantages.

From this study of the climatic conditions of Colorado and especially from the experience of the profession here, we are led to believe that benefit or complete recovery may be expected in the following classes of cases:

In all cases of an inherited tendency to tuberculosis, as a prophylactic measure; in tuberculosis of the bones or parts of the body other than the lungs, with a view to prevent pulmonary involvement; in early pulmonary tuberculosis when it occurs in persons who are not of a markedly nervous type and when the disease is not accompanied by persistent high fever and is of a chronic rather than an acute type.

In cases of moist nasal catarrh, when not caused by nasal deformities; in bronchial catarrh, with or without asthma, especially in children and young adults; in most cases of purely nervous asthma and in many cases of hay asthma.

In chronic empyema and unresolved pneumonia and in many cases convalescing from pneumonia, who are under fifty years of age. If the patient is old, has heart disease, or is greatly emaciated, a sedative climate is better, at least until a fair amount of strength has been gained.

Patients who are convalescing from other acute diseases or suffering from physical or mental exhaustion, from overwork, worry, want of exercise, malarial affection or tropical cachexia, mild cases of anemia, most cases of glycosuria and many cases of nephritis are improved by this climate. Articular rheumatism is less frequent and muscular rheumatism more common here than in the east.

Diarrhea and digestive disorders are not as prevalent and trachoma is very rarely seen.

But there are two sides to this question, and we must not fail to mention the contra-indications. Some of these relate to the patient and others to the disease.

Patients over sixty years of age should not, as a rule, move to places of great altitude, because their muscles have lost their elasticity and cannot accomodate themselves to the change.

The muscular fibers of the heart and arteries are of especial importance in such cases. More work is thrown upon the heart and arteries and most organic diseases of the circulatory organs are made worse. It is generally stated that this climate is contraindicated in cases of weak or congenitally small heart, and in functional disturbances of the heart without organic lesion. My own experience is not in accord with this idea.

I believe the constantly increased work thrown upon the heart, together with the increased gain in vigor, which is usually present, have the effect of so increasing the muscular tonus and regulating the nervous supply of the heart as to render its action more nearly normal.

The exhilarating effect of altitude on the nervous system is well known. Many residents of this locality are frequently obliged to change for a time to places of less elevation. If they do not they suffer with insomnia. For this reason persons of an extremely nervous type seldom improve here, although some cases of a gloomy tendency are much benefited.

As contra-indications in certain diseased conditions we will mention:

Consumption, with a tendency to rapid breaking down of tissue, associated with high fever. Cases of acute phthisis or phthisis florida, and those in the advanced stages of the disease, and all cases with a persistent high temperature, even in the early stages, are not improved by this climate. We believe in such cases the end is often hastened by the change rather than retarded.

Intermittent attacks of high temperature do not contraindicate resort to altitude, unless the temperature is excessive or the patient extremely nervous. Hemoptysis is not a contra-indication. Structural alterations of the heart, atheroma of the blood vessels, aneurism or emphysema, either alone or as complications of other diseases, forbid removal to altitude.

I cannot refrain, in this connection, from making some suggestions in regard to the home physician's duty to his patient in placing him in the care of some honest, legitimate physician at his point of destination. If the home physician should have no personal knowledge of such a professional brother in Colorado, the medical directories will enable him to form some kind of an opinion.

Very often, too often, in fact, patients come here uninstructed, and before they have time to leave the dêpot some big, fat drummer will offer his assistance in finding them comfortable quarters, and before leaving them will have informed them that he, too, came here for his health, and that three months ago he was so emaciated by tuberculosis that he could not stand, etc., but he will always end his story by the statement that he was treated by the world-renowned specialists of the "Cure All" Medical Co., and, as they had done so much for him, he will call next day and introduce strangers to these wonderful specialists. The result is easy to imagine; the patient yields, a positive cure is guaranteed in thirty to sixty days, and the company get $50 or $100 of the sick man's money to start with, and a fair chance of absorbing most of the balance, leaving him to starve himself that he may be able to keep his contract with them.

Another mistake physicians make, is to advise their patients not to take any medicine or place themselves under the care of the doctor here. Patients often tell me this is their physician's advice.

If a physician's advice as to suitable food, clothing, baths, exercise, employment, location, ventilation and care of the sputum is of use to the patient in the East it ought to be of equal service here, or, if the patient has been in a measure sustained or his *vis medicatrix naturæ* increased, by a judicious administration of strychnine, iron, arsenic, fatty emulsions or any constructive medicament in the East, it certainly seems to me, it would not be the part of wisdom to suddenly withdraw any or all of these adjuvants.

A sick man in Colorado needs medical care just as much as he does in the East, and the same medical care aided by the atmospheric conditions of the place will, in suitable cases, result in much greater benefit to the patient here than there.

The benefit of Colorado climate to a tuberculous patient will depend very much on a proper understanding on his part of the kind of life he should live here. A tuberculous patient will do better in the East with plenty of food and home comforts than in Colorado on a starvation diet. He had better live out of doors in the East than shut up in a stuffy room in Colorado.

DOES ABSENCE OF EXTERNAL INJURY LEGALLY DEMONSTRATE FRIGHT OR MENTAL ETIOLOGY?

BY JAMES G. KIERNAN, M.D.,
OF CHICAGO.

Judges of the State Supreme Courts have evinced a tendency to deny etiological value to anguish, fright or other psychic factor as a result of which damages can be obtained. In the case of Braun *vs.* Craven,[1] the Illinois Supreme Court emphasized this view. By a not unnatural evolution, attorneys have sought further to develop this view into the claim that external evidence of injury being absent, the injury resulting from an explosion must be regarded as due to fright or other psychic influence, and hence not a fitting subject for compensation under the views enunciated by the Illinois Supreme Court in the case just cited. This standpoint was taken by ex-Judge Sears and was sustained by Judge Chytraus, of the Supreme Court of Chicago, in the case of Baudler *vs.* People's Gaslight and Coke Company. The case, however, was appealed by Waters, Johnson & Baker, the plaintiff's attorneys, to the Appellate Court. The circumstances of the case, in which I was an expert for the plaintiff, are as follows:

The plaintiff brought suit against the defendant for personal injuries alleged to have been sustained March 6, 1899, by an explosion of gas in the basement of his house in Chicago. He was a German by birth, a carpenter by trade, who had built his own house and piped it for water and for sewerage, but not for gas. The defendant company had a gas main in the street in front of the house, but no connection pipe ran from the main to the house. For at least two months prior to the explosion this main had been leaking in front of the house. Several of the neighbors had noticed the smell of escaping gas. One of them told a man who read the meters of defendant in her house of the defect and he replied: "It is going to be fixed in a short time." Another neighbor gave evidence to the same effect. For two months the gas escaped through this leak, passing into the cellar and sleeping room of plaintiff's house. He smelt the odor but says he did not know what it was.

March 6, 1899, after a very uncomfortable time that night, he and his wife went down into the cellar to find out whence the smell came. They located it near a post. The wife struck a match on that post and an explosion occurred which moved a stove standing near by at least two feet and changed the position of the carpenter's bench a foot or more. When the match was struck the plaintiff was standing from four to six feet distant from his wife. It seems that neither he nor his wife were thrown down by the shock. A witness (whose house was fifty feet from that of plaintiff, and who was in his basement when the explosion occurred) says: "A big oak plank fell down. It was a big explosion all right."

[1] 175 Illinois, 401.

The plaintiff received no visible injury. Before the explosion he was a healthy man in body and in mind. His family physician says: "He was in good sound condition up to the time of the accident, so far as I know." Five other witnesses who had known the plaintiff for years testified that before the accident he was not nervous but healthy, sociable, a kind man, interested in his work. Immediately thereafter his physical health became impaired and he lost his mental balance. He became suspicous of every one, feared his wife and daughter would poison him, and was irritable, wandering from home and always complaining of smelling gas. He was taken to a hospital where he remained a short time. He went to Europe saying he would stay there all his life, but came back within six weeks. He is no longer a trustworthy or steady workman. His memory is defective. The only objective symptom I testified to finding was a heart murmur: "The disorder prevented one of the valves of the heart from closing and acting properly. If the heart were perfectly healthy before the explosion, and this occurred afterwards, I should be inclined to refer this murmur to the explosion. It indicates a weakness and irregularity of one of the valves of the heart. It shows the valve leaked. In the absence of other causes in a healthy person I should ascribe it to the explosion."

At the close of plaintiff's case the trial court, on motion of ex-Judge Sears, peremptorily instructed the jury to return a verdict for defendant. For this ruling an appeal was perfected. Presiding-Justice Ball, who delivered the opinion of the Appellate Court, said therein: "When a case is taken from a jury by a trial judge and comes to us for examination on appeal, the question to be determined is—the whole record being considered—was there competent evidence, which, from its reasonable intendment and inference, fairly tends to make out plaintiff's case. It was not for the trial judge, nor is it for us to weigh the evidence. This is a well-settled rule of our Court. Any other rule would leave the trial by jury to the judgment and discretion of the presiding judge, a result repugnant to the spirit of our jurisprudence and forbidden by our State Constitution and Federal Constitution.

"The evidence clearly establishes negligence of defendant as charged in the declaration. For at least two months prior to the explosion gas had been escaping from this main. Those who passed by noticed it. The evidence also tends to prove that the defendant through its employees, were twice notified of this leak, long enough before the accident for its repair, had reasonable diligence been used in that regard. No disturbance of the street was shown after the time the main was laid; from the evidence it would seem that this leak occurred because of faulty construction. If so, the person injured thereby, without fault on his part, has a right of action against defendant for all the damages sus-

tained by him therefrom, even though the defendant had no notice of the defect.

"This main was laid in the street with the great and exclusive privilege of supplying that part of the city with light for private gain. Through this main defendant passed gas known to be highly explosive. It was the duty of defendant to keep the gas within the main and connecting pipes until it was delivered to the consumer. To this end the defendant was not only bound to lay down a main of good material, with skill and care, but it was also bound to inspect the main from time to time and with such frequency that the defects caused by use or accident might be repaired with reasonable despatch. The care required of defendant is commensurate with the subtle and dangerous character of the material in its exclusive charge and control.

"Some of the authorities[1] hold that the mere fact of the escape of gas from a place under the control of a gas company is sufficient evidence to raise the presumption of negligence upon its part.

"The evidence shows that the house of plaintiff was not piped for gas; that he was not a consumer of defendant and that the gas escaping from this defective main passed into his cellar. We are satisfied the evidence shows such negligence upon the part of defendant that the case should not have been taken from the jury upon this point.

"Was the plaintiff guilty of such negligence as warranted the trial court in directing a verdict for defendant? It must not be forgotten that plaintiff was upon his own property. Therefore he was under no obligation to watch lest he might be injured by the unlawful act of defendant in flooding his premises with explosive gas.[2]

"Plaintiff says that while he detected the odor of escaping gas he did not know what it was. Upon this appeal, his statement in that particular must be taken as true. Not knowing the character of the odor he was consequently ignorant of its dangerous qualities. He did not create the situation, and he was justified in attempting to solve the mystery which rendered his house uninhabitable. Under these circumstances, if in so doing he had himself lit the match which caused the explosion he would not thereby be guilty of negligence, which, as a matter of law, would deprive him of redress as against the wrongdoer. Believing this to be the law, we need not enter into the vexed question as to how far he was responsible for the act of his wife in lighting the match. It is presumed he knew she was going to light it. A presumption arising from the fact that they went into the cellar together to ascertain the cause of their discomfort. The evidence fails to show that he knew in direct terms what she was about to do. She was not necessarily his servant, nor is he conclusively presumed to be responsible for the acts she might commit without his knowledge. Her contributory negligence cannot be visited upon plaintiff unless she was at the time his servant or agent.

"If the occupant of building knew gas had been escaping for some time and sent his servant into the cellar with a light whereby an explosion is produced, this will be evidence sufficient to support a verdict for defendant, but it will not warrant a judge in directing a non-suit.[1]

"Granting that the plaintiff was not guilty of contributory negligence, the trial judge in directing a verdict for the defendant, must have assumed that the plaintiff received no physical injury, but that all of his disability following the explosion, and which date from that time, resulted purely and solely from fright. The evidence goes no further than this, that the plaintiff received no *external* physical injury. He was struck by the exploding gas only. The force of such an explosion depends upon the strength of the explosion and the proximity of the party to the point of the explosion. That one may be seriously injured or even killed by such an accident without apparent external injury, we know, if we are permitted to rely upon common observation and knowledge. That gunners are sometimes disabled by the atmospheric concussion resulting from the discharge of heavy artillery, we must believe from personal observation and from the unvarying statements of writers upon the subject. One may be internally injured without external indications and that mind and body may be impaired by internal lesion or weakness as well as by external violence. The disability of the plaintiff followed the explosion so immediately that the inquiry at once arises, Did they not proceed from that cause?

"It seems to us to be far from true that all reasonable minds viewing this evidence would reach the conclusion that "the heart murmur" was caused solely by fright. If they would not so agree then the act of the trial judge, in directing a verdict for the defendant, is wrong. But we are not left to supposition in this case. Dr. Kiernan, in speaking of the condition of plaintiff, says: "A sudden change has occurred for which there is no adequate cause given, other than the explosion, which might have been sufficient to produce the condition found. If the heart was perfectly healthy before the explosion and this murmur occurred afterward, I should be inclined to refer this murmur to the explosion."

"This testimony tends to prove that the physical impairment of the plaintiff was the direct effect of the explosion. Its credibility and weight should have been submitted to the jury, whose duty it is to pass upon all questions of fact.

We have examined the cases cited for defendant, especially Braun *vs.* Craven, and are of the opinion that under the facts here presented they are not controlling." The judgment of the Superior Court was therefore reversed and the case remanded.

COMPRESSED-AIR ILLNESS, OR CAISSON DISEASE.

BY CHARLES J. ALDRICH, M.D.,

OF CLEVELAND, OHIO;

PROFESSOR OF MENTAL AND NERVOUS DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS, CLEVELAND; NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND DISPENSARY; NEUROLOGIST TO THE CLEVELAND CITY HOSPITAL.

Man, dwelling in the valleys and low hills through countless centuries, has attained a physiology which allows but slight variation from an atmospheric pressure of seven hundred and sixty millimetres of mercury. He early learned that any great departure from that pressure produced disturbances of his savage economy that were startling and unpleasant.

Some of the more hardy found that if they ascended the mountains, reaching a height of a mile and a half or two miles, the respiration became rapid, the heart quickened, the blood pounded in the temples producing headaches, oftentimes blood flowed from the nose, eyes and mouth, and there was nausea and vomiting. But all of their wanderings over the surface of the earth furnished them no example where the air was sufficiently compressed, because of a low altitude, to produce the slightest physiological disturbance. The valley of San Diego County, California, three hundred and sixty feet below the level of the sea, does not convey to the traveler any appreciable sense of air compression. In the deepest valley known to the world, in which lies Lake Assal, east of Abyssinia, seven hundred and sixty feet below the level of the sea, no unpleasant effects of air compression is to be discerned.

Not all creatures of the earth are subjected to this peculiar limitation of atmospheric pressure. It is recorded of the great naturalist, Humboldt, that after climbing the Cordilleras he saw the condors soaring majestically at the noble altitude of eighteen thousand feet. From this dizzy height, now and then, they would stoop to the surface of the sea, in a few moments of time, passing through a range of barometric pressure far greater than that between earth's highest mountain peak and her lowest valley.

It is known that fish live in the deepest portions of the sea and sustain the enormous pressure of miles of superimposed brine. When scientists began to bring these fish up from the profound depths of the ocean they were surprised to find that the bones were spongy and apparently ill-fitted to withstand a pressure of tons to the square inch. It was later assumed that it was the expansion of the compressed fluids and gases, which had disentegrated and rent apart the most solid portions of their piscatorial anatomies.

That it is possible for man to acquire an ability to live in comfort and health in very high altitudes is evidenced by the fact that the Quichuas, a healthy, vigorous, broad-shouldered, long-chested race of Indians, inhabit the high peaks of the Andes, fifteen thousand feet above the level of the sea. Also the "Cods" a Tartar race, live on the high plateaus of Thibet, and are people celebrated for their strength and suppleness; in fact, "Cod," in their language, means strength.

That man can adapt himself quite rapidly to high altitudes is shown in the records of the ill-fated Austro-French expedition to Mexico in 1863. It is recorded that the troops stationed on the high plateaus of Anahuac become quickly and completely acclimated.

The same curiosity or fancied necessity which led early man to the mountain tops soon caused his progeny to attempt the bottom of the sea, yet we are told that diving bells were not invented until the beginning of the sixteenth century. While literature affords some fragmentary observations upon the effects of compressed air on man while going down in diving-bells, yet we find but little that is satisfactory until after the year of 1839, when the French engineer, M. Triger, put to practical use the great principle of compressed air as a safe barrier against water and quicksand. Large bodies of coal were known to exist beneath the valley of the Loire, but above it was a hitherto impassible layer of water and quicksand. The ingenious Frenchman was equal to the task. By the use of compressed air, shafts were carried down in safety to the coal below, and one of the greatest problems of engineering was solved.

The application of the principle to pier-building for bridges was first made by Mr. Hughes, an English engineer, in 1850. Compressed air was not used in tunnel building until 1879. This was in the construction of a tunnel beneath the Hudson River, designed to connect Jersey City with New York.

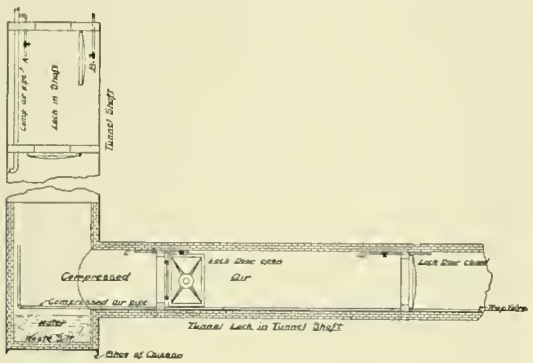
Soon after this principle was applied to these various engineering undertakings it was discovered that if the workmen were subjected to too high pressure or remained too long under pressure, as low even as one additional atmosphere, a peculiar, yet tolerably constant set of symptoms developed when they returned to a normal atmospheric pressure. Among scientific men this disorder has received various appellations,—"diver's paralysis," "caisson disease," and "compressed-air illness." Among the workmen it is known by various names, each usually significant of some prominent symptom. The "bends," when the pains are in the bowels or extremities; "chokers," when dyspnea and a peculiar choking feeling is present; "staggers," when vertigo is pronounced; "prickles," when the skin is the seat of a prickling sensation, believed by the workmen to be air coming through the skin; the "fits," when convulsions appear.

Before passing to a consideration of the disease I desire to call your attention to these sectional drawings which I have prepared, hoping that they will aid in the explanation of this interesting phase of submarine engineering. Some caissons are made of wood, others of iron or steel. Steel and iron caissons are usually cylindrical. A caisson may be compared to a huge box with the bottom turned upward, and

the open space underneath to the working chamber. It is constructed on ways, from which it is launched like a ship, towed to the desired spot, weighted with concrete and masonary until it sinks and its box-like edge, armed with an iron cutting shoe, rests on the bottom of the lake or river. Air-compressing engines are set to forcing air through the compressed air pipe into the working chamber. Within the chamber this pipe is provided with a trap valve which closes from its own weight and prevents the escape of compressed air in event of an accident to the machinery, thus providing for the safety of the workmen. The air is pumped into the chamber until all of the water has been forced out and the lake's soil lies dank and bare at the bottom of the working-chamber. The chamber is now ready to receive the workmen through man-holes left in its construction and which are provided with locks. These locks are supplied with two strong doors which swing downward and have air-tight fittings. Each one is pierced by a pipe provided with an air-cock within the lock.

The passings into and out of the working-

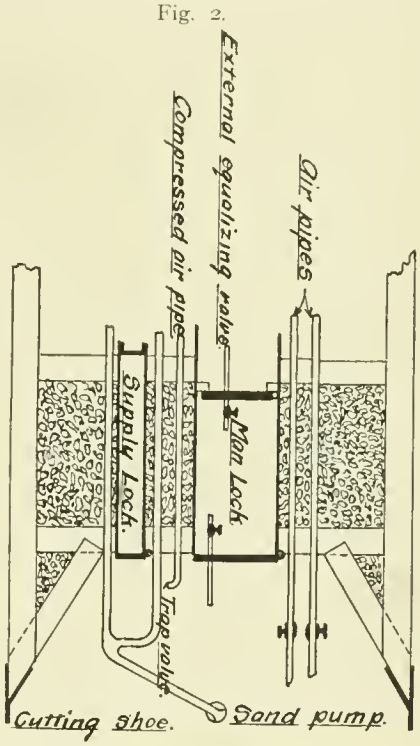
Fig. 1.



chamber are respectively called "locking in" and "locking out," and as around these transitions is grouped much of the etiology of this disease, I desire you to obtain a correct idea of these procedures. When the caisson is towed to its position and sunk, the lower door of the lock is closed and the upper left open, as is shown in the shaft of Fig. 1. Air is then forced into the chamber until the water is displaced and the chamber is ready for the workmen. To go into the compressed-air chamber,—"locking in,"—the men pass through the upper door into the lock, close the door and the air-cock B (Fig. 1), and then open the air-cock A, which allows the compressed air to enter the lock until the density of the air in the lock equals that of the working chamber below, when the door falls of its own weight and they are free to enter the chamber. In "locking out" the process is reversed. The lock is entered from below, and the lower door and cock A closed. Cock B is then opened to allow compressed air to escape until the lock pressure equals that of the atmospheric air, when the door falls, allowing the workmen to pass.

When the lake bottom has been well excavated the workmen open one of the air-cocks in the air pipes, which are seen in the working-chamber of Fig. 2, and allows some of the air to escape until the great weight of the caisson causes it to settle deeply into the soft mud and silt. In the meantime, and above the water-line, the masonry of the piers is building on the top of the caisson, leaving passageway for men and material to the working-chamber below. The great weight forces the caisson downward, and is called, "settling the caisson." The workmen excavate the silt, which is carried to the surface by means of sand-pumps, blow-pipes, and buckets, until they are again down to a level with the cutting shoe of the caisson, when the air pressure is once more lowered and the caisson allowed to sink. This

Fig. 2.



Sectional View of Wooden Caisson and Working Chamber

maneuver is repeated until a solid foundation is found for the pier. Concrete is then "locked in" and the whole working chamber is filled; and lastly the locks are removed and replaced by the same material. When the shaft is sunk for tunnel-building the process varies only in detail.

Did time permit, it would be interesting to recount the early observations of compressed-air illness.

Since the beginning of the great water tunnel at Cleveland, five miles in length, underneath the bed of Lake Erie, I have had the opportunity to observe and study more or less completely, over fifty cases of caisson disease.

On request of Dr. Sollmann, the secretary of the section, I shall attempt a discussion of the clinical phases of this interesting and remarkable

disease, using the observations of these cases as a basis for my remarks.

The cases observed presented almost every phase of the affection, and varied in severity from a transient attack of pain or giddiness, to violent convulsive seizures, rapidly developing coma and death. Inquiry of the patients and also of Dr. Frank Roth, who was for some months stationed in Crib Number 2, reveals the fact that almost every one of the men at work experienced attacks of pain in the joints, or the flesh, or abdomen, vertiginous attacks, dyspnea with choking sensations, and attacks of prickling of the skin. The majority of these fifty cases observed were merely exaggerated instances of the almost daily experiences of the "sandhog man."[1]

In consulting my records I find that four suffered from hemiplegia, fifteen from paraplegia, two from monoplegia, and nine from violent vertigo. In the remainder pain was the reason for their entrance of the hospital.

The transient nature of many of the symptoms is very puzzling. Pains after coming out from "the air," as has been remarked, is so common that ordinary attacks are thought little of by the workman, who takes his refreshments and sleep and returns to the work. These pains may be in any part of the body, but are usually about the large joints or abdomen. They may be so slight as to cause but a transient discomfort, or so severe as to be beyond human endurance.

Not a few cases of transient hemiplegia, paraplegia and monoplegia are observed. Indeed so evanescent are the symptoms that the workmen may be completely paralyzed in some of his members soon after "locking out," yet so far recover as to go down two and one-half hours later with his regular "shift." Eight of the fifteen cases of paraplegia observed averaged in duration but four days; two made partial recoveries, two are hopelessly crippled, and three died from cystitis, bed sores, and exhaustion. In every case of paraplegia that I have examined, however slight, there was paralytic retention of the urine. Two case of paralytic retention of urine without other paralysis were observed. Aphasia, usually quite transient, was observed four times, once alone, once with paraplegia, once with a combined paraplegia and hemiplegia, and once with a right hemiplegia.

Vertigo, in every degree is met with. It is so common as to cause few of those attacked to stop work on account of the "staggers." I recall one patient who worked eight hours under a pressure of thirty pounds additional[2] on his very first shift. When he came to the air he said he thought the top of his head was blown off. His vertigo was intense and he could not stand. He soon became unconscious and remained unconscious and insensitive for four days.

The following abstract of the case of Thomas R., seen at the City Hospital, is given principally to illustrate a case of the "chokes," but of great interest because of the number and variety of symptoms.

The patient began working in the waterworks tunnel November 15, 1899. December 22, after being in the "drift" eight hours, he came up feeling well as ever, sat down at the table for supper and almost immediately his legs, from the hips down became numb and at the same time he experienced dizziness. Upon attempting to stand he found that all muscular power was gone from his legs and he promptly fell. He was placed in a hot room and his legs rubbed. The next afternoon he was brought ashore and sent to a hospital. He was unable to pass urine from time of attack until two or three days later. When catheterized at the hospital a large quantity of thick turbid urine was removed. After four or five catheterizations the urine passed from him uncontrolled, from paralytic incontinence of the spincters. This condition continued. He could, however, feel the urine passing through the urethra. Feces were discharged without patient's knowledge or control.

About the fifth day sensation returned to his legs as suddenly as it had departed, and about the same time he became able to move those members to a very limited extent. A little later pains appeared in the large joints and some of the muscles, especially those of the thighs and abdomen, and were so severe, at times, as to be almost unbearable. Occasionally they would appear in the head and were accompanied by blindness, nausea and vomiting. At times, when the legs were extended and patient on his back, a leg and thigh would suddenly be brought to extreme flexion causing excruciating pain, mostly in the abdominal muscles. Again he would experience what the workers call the "chokes," which he said was even harder to bear than the other pains. The sensation was such as would be produced by a tight grip about the neck which almost strangles. It was accompanied by nausea, usually with inability to vomit. With it came cramp-like pains in the abdomen and great difficulty in breathing. The sufferer died February 27, 1900, of exhaustion, hastened by cystitis and a large bed sore over the sacrum.

From a study of these cases I can briefly sum up the symptoms as they appeared to me:

Symptoms.—The symptoms of true compressed air illness occur only during or after the patient's return to the normal atmospheric pressure. In point of time they may occur during the transition from the compressed air to the normal atmosphere,—"locking out,"—immediately after "locking out," or they may be delayed several hours. Every grade of caisson disease may be met with, from transient twinges of pain in an about the elbows and knees, to convulsions, coma and death. The pain is intense, with remissions and exacerbations; particularly severe in the stomach and about the large joints;

1 Pressure worker, or, less elegantly, "sandhog man," is the name these workers apply to each other.

2 By this is meant 30 lbs. in addition to the one atmosphere at the sea level.

the victim is bent double with pain, hence the term "the bends." The pain is intolerable.

The duration of the disease depends largely on the type. The neuralgic cases last from a few minutes to five or six days, although the usual duration is about twelve hours. The duration of the paralytic cases can only be measured by the amount of damage sutained by the central nervous system. Some paralytic cases recover quickly; others perish from exhaustion and cystitis after a lingering, painful illness. Many are permanently crippled. The lethal cases are usually of rapid onset, and death is swift and sure. Some of the brain types may be transient, and present headaches, giddiness, double vision, incoherence of speech, and sometimes unconsciousness and convulsions.

The paralytic forms are atypical, with the greatest tendency or paralysis of one side or both lower limbs. The bladder and bowels are almost certain to be weakened or paralyzed. This often occurs when little or no evidence of paralysis exists elsewhere. Any member of the body may, through paralysis, lose the power both to move or feel, and yet be the seat of atrocious pain, a genuine *anesthesia dolorosa*.

The fatal cases, frequently convulsive from the start, are very severe, and usually develop a deepening coma which ends in death.

Aside from the symptoms proper of caisson disease we have a number of disturbances of minor importance. Most prominent among these are the symptoms in connection with the ears. These symptoms, however, appear during the process of "locking in" and "locking out," and consists of pressure exerted on the ear drums either externally while "locking in" or from within outward while "locking out." Not infrequently the ears are "blowed out" as the workmen express it, in which case a small perforation of the drum takes place. This is looked upon by old hands to be a fortunate occurrence, since they will no longer be troubled with the "air in the ears." While undergoing compression the drums of the ears should be inflated, and while undergoing decompression rapid swallowing is necessary. If the Eustachian tubes are closed through some catarrhal trouble or cold severe pain and rupture of the drum is very liable to occur. It is quite possible that some of the cases of violent vertigo not infrequently observed, are due to the effect of air upon the otic structures.

Etiology.—The causes of caisson disease may be divided into predisposing and exciting.

The predisposing causes are those which relate to the workman's bodily condition and habits. There seems to be a special predisposition on the part of some persons who are affected by a short exposure to a pressure that ordinarily affects no one, while others appear to enjoy a surprising immunity although exposed to all of the causes recognized as most active in producing this nineteenth century disease.

It was early remarked that the liability to caisson disease is very much greater in those engaging for the first time in "pressure work." It is also a matter of record that those who begin with the work when the pressure is low, and continue at the work during the sinking of the caisson, and are daily subjected to the gradual increase of pressure, are much less liable to suffer than those engaging when the pressure is high. That this apparent immunity is only relative, is shown by the fact that some very serious attacks occur in old hands, and very often without discoverable cause.

Dr. Andrew H. Smith, while observing the cases of caisson disease that developed during the sinking of the piers of the East River Bridge, in New York, was convinced that individuals with a tendency to corpulency were especially predisposed to the disease.

Jaminet insisted, and it is now a common observation of experienced men, that to enter the caisson while fasting is hazardous. Very unpleasant effects are oftentimes felt on entering the caisson with a full stomach, before the lapse of from forty to sixty minutes after the meal.

Douchy and others have maintained that alcohol is a potent cause of the attacks. Disease or any depression of the vital forces from fatigue, loss of sleep, debauchery, or alcoholic excesses, no doubt increases the liability to an attack.

The exciting causes of the caisson disease are those excitations which determine the advent of the attack. There are seven paramount excitants to the disease which I will name in the order of their importance: (1) Degree of atmospheric pressure; (2) length of sojourn under such pressure; (3) the rapidity of the transition from the condensed to the normal atmosphere—"locking out;" (4) insufficient lapse of time between leaving the condensed air and returning to the same; (5) lack of sufficient ventilation of the areas under pressure; (6) exposure to a damp, chilly air after leaving the lock; (7) active muscular exertion after "locking out."

It is very doubtful if the disease ever occurs in workmen subjected to less than fourteen pounds pressure, and both its severity and frequency increase in a direct ratio to the rise in the atmospheric pressure multiplied by the length of time exposed to such pressure. Men can usually work with comparative safety for a period of eight hours under a pressure of from fifteen to twenty pounds in addition to the one atmosphere of the surrounding air; under a pressure of twenty to thirty pounds, six hours divided into two "shifts" of three hours each; under a pressure of thirty pounds, two hours divided into two "shifts" of one hour each; but under a pressure of from forty to forty-nine pounds, two "shifts" forty minutes each are all that can be borne with any degree of safety. The caissons at Memphis were sunk one hundred and twelve feet below the water level, the deepest caisson work, I believe, that then had ever been accom-

plished, and the pressure reached the highest known to caisson sinking—forty-nine pounds. The Eads bridge at St. Louis, also demanded a pressure of almost the same amount. One of the shafts of our water tunnel, now in course of construction, is one hundred and sixteen feet deep, but because it is in clay, needs little more than forty pounds pressure, enough, being in clay, to furnish many cases of the "bends."

The necessity for a proper lapse of time between the "shifts" of workmen is very important and should be insisted upon. In the too rapid transition from the condensed to the normal atmosphere—"locking out"—lies a most frequent cause of caisson disease. In fact, it is quite certain that if sufficient time were allowed for "locking out," the accident would never occur unless the exposure to pressure had been prolonged beyond the before-prescribed limit of time. A time limit should be fixed for "locking out," allowing five minutes for the first twenty pounds pressure and for each additional pound one-half minute should be added.[1]

Experience has taught "pressure workers" that hot coffee and hot blankets to prevent chill are very useful. At Rob Roy, Ark., fourteen men came out of a shaft and laid down on benches in a poorly constructed building, and as the weather was warm, went to sleep with little cover; three hours later a "norther," one of Arkansas' cold wind-storms arose, and nine out of the fourteen men were severely and immediately attacked by the "bends." This is a good illustration of the effects of cold after coming out of the caisson.

Few authorities even mention the importance of active ventilation of the condensed-air area as a preventive of the disease. My attention was called to it by a patient, an engineer, who tells me that whenever experienced workmen strike clay they grimly remark, "It's full of the bends," notwithstanding that they are aware that clay demands less pressure than sand. In the sand at Memphis, although the pressure reached forty-nine pounds, there were fewer cases of "bends" than in our clay-walled tunnels, with a pressure of about thirty pounds. This was, no doubt, due to the method of excavating sand by the use of blow-pipes, which demands a rapid change of air in the caisson. It is quite probable also that the loss of air through leaks in the caisson causes a greater amount of air to be forced into the caisson to keep up the pressure, thus perfectly ventilating the narrow place. It is also certain that the use of iron cylinders, instead of the less tightly made wood caissons, gives rise to "bends" more frequently on account of the lessened ventilation. Practical workmen are all aware of this fact.

[1] Since the above was written, examination of a number of cases and conversations with Dr. Frank Roth causes me to believe that it is not so much the decompression as it is the length of sojourn under the pressure that determines the attack. The lock tender is an instance of this fact. He passes in and out with a reckless regard to time, is never long under pressure, and, as has been frequently remarked by other observers, *never is attacked.*

The first scientific writer who called attention to the importance of ventilation was Hunter, whose thesis concerning the disease as observed during the construction of the Forth bridge, unfortunately was not published. He is quoted by Snell, whose carefully recorded observations made during the construction of the Blackwell tunnel, London, are of great value.

The following table, taken from Snell's book, "Compressed-Air Illness" will serve to illustrate the tremendous importance of ventilation, which our tunnel and city engineers entirely overlooked until nearly half the work was completed, and many workers maimed and killed by an ignorance or carelessness little less than criminal.

Cubic feet of fresh air per man, per hour, in average daily shift.	Number of days.	Cases of illness.	Estimated cases of illness for one hundred days.
Below 4,000	56	16	28.5
From 4,000 to 8,000	47	9	19.1
From 8,000 to 12,000	71	8	11.2
Above 12,000	41	0	0

Years ago, before electricity was used to light compressed-air chambers, the soot from the lights was one of the terrors of the workmen. The respiratory tract became so saturated that for many months after the expectoration would be tinged with black. It was discovered that this was due to the fact that air under pressure does not circulate. Yet we find in the lake tunnels the engineers were ignorant of these facts, or they have little reckoned the value of human life, for the only pipes conveying air to the tunnel ended just beyond the lock, while the workmen were as far as seventeen hundred feet distant at the face of the tunnel. And they gravely wondered at the City Hall why there was an explosion in the tunnel and a few lives lost!

When one great explosion took place in the tunnel with a loss of eleven lives, the pipes would admit only nine thousand cubic feet of air per hour to the eight men and two mules. Allowing the mules the consumption of air equal to seven men, we have but six hundred cubic feet of air per man. We have no law in Ohio for the protection of men working in tunnels, but I would suggest that the Humane Society ought to have looked after the mules!

On leaving the caisson there is a great increase of heart and lung action; the subject often gasps for breath; he is manifestly ill-fitted for any severe exertion, and abundant experience has demonstrated that many cases have been caused and others aggravated by the error of having the locks low down in the shaft instead of at the top. Triger demonstrated at Challonnes that when the men made the ascent of seventy feet under pressure to the lock at the top of the shaft, it was done more easily than in the open air. Elevators are now used in deep shafts, and certainly their use is attended by a lessened number of attacks.

A NEW CASE OF CHLOROMA WITH LEUCEMIA, WITH A STUDY OF CASES REPORTED SINCE 1893.

BY GEORGE DOCK, M.D.,
AND
ALDRED SCOTT WARTHIN, M.D.,
OF ANN ARBOR, MICH.

(Continued from Page 976.)

OBSERVATIONS ON CHLOROMA SINCE 1893, BY DR. DOCK.

Since 1893 twenty-one cases of chloroma have been reported more or less fully. Two more were mentioned by Beneke and Drozda in discussions. Bramwell refers to probable cases known to him, as well as an interesting case described in his paper referred to in this article, in which some green lymph glands were found in the body of a patient who died of acute leucemia. Dr. Trevithick (personal communication) has heard of another case. No doubt some of the cases of symmetric tumor of the orbit, examples of which are frequently reported, are really chloromatous. I have heard indirectly of two unreported cases of chloroma observed in German clinics, in one of which there was leucemia. Many authors reporting cases of chloroma refer to the greenish color of the lesions in ordinary cases of leucemia. It is not necessary to discuss this particularly, but I shall refer later to a most interesting case observed by Türk.

Sex, Age, Duration.—In the present series of 22 cases there were three females, 19 males; or, in both series nine and 29 respectively.

The average age was 18.8 years, or three and one-half years older than in the former series. The average is raised by the occurrence of four cases in persons between thirty-eight and fifty-two years; 15 cases were less than twenty-five years old, 12 less than sixteen, one ten months.

The average duration was 5.5 months. In 10 it was four months or less, two each being stated as one and two months. In one case it was one year, another thirteen months, in a third one and a half years.

Location of the Chloromatous Growths.—Regarding the seats of the peculiar green formations, the data in the later cases resemble in general those of the earlier series. Some part of the head was affected in all but two of the cases in which the examination was complete. In Bramwell's case and our own the skull was not examined. In Gümbel's case the orbit, temples, and periosteum of the base of the skull were not involved, but there were green masses in the dura of the brain. In Rosenblath's two cases the orbital tumors were not adherent to the periosteum, but seemed to proceed from the lids (in one also adherent to the optic nerve), and the cranial bones and periosteum were free from chloroma. In one of the cases the nasopharyngeal space contained green masses. In Sternberg's case the head showed no involvement. The most frequent seats in the head were the orbits (12 cases), usually involving the periosteum; the dura or sinuses (9 cases); temporal bone, especially in the auditory region (7 cases); the temporal fossa (8); less frequently the sphenoid (3); ethmoid (2); the choroid plexus (2); the nose, nasopharynx, maxillary antrum, pterygoid fossa, soft palate, gums, mastoid cells. The vertebræ were affected in 9 cases, usually in the periosteum of the bodies, sometimes in the dura, sometimes the periosteum of the processes, or the fat in the vertebral canal. The sternum was affected in 7 cases, in the periosteum either front or back, or eroding the bone (Rosenblath); sometimes the growth was continuous over the sternum, clavicles, and ribs. The ribs were involved in 8 cases.

The other bones were not so regularly examined, but green infiltrations or tumors were found in the periosteum of the sacrum, coccyx, iliac bones and the bones of the extremities, in the diploë of the skull, and in various flat and short bones. Chloroma was found in bone-marrow in 7 cases. The liver was the seat of green growths in 8 cases, the kidneys in 12, spleen 3, stomach once, (Weinberger), intestines three times (twice in the appendix). The lungs, pleura, pericardium, endocardium, the heart muscle (Dunlop) were rarely affected, also the serous and synovial membranes. The lymph glands were frequently involved, but in one case (Klein and Steinhaus) it is expressly stated that the lymph glands were without pathological changes, the growths affecting the periosteum of the bones of the head and trunk, the kidneys, prostate, and bone-marrow of the femur. The cervical glands were most often involved (11 cases); less frequently the axillary, inguinal, submaxillary, mediastinal and bronchial glands, and those in the portal fissure of the liver, the lesser curvature of the stomach, around, above, or behind the head of the pancreas, the prevertebral and mesenteric glands. Other locations were: the conjunctiva, tonsils, mucous membrane of the epiglottis, larynx, arytenoid cartilages, thyroid gland, thymus, bladder, prostate, urethra, ovaries, mammæ, pancreas, diaphragm, pelvic connective tissue and periosteum; the insertions of many muscles, as the temporals, intercostals, psoas and dorsal muscles; the brachial plexus, the adventitiæ of arteries and veins, or even all the coats of the vessels, the subcutaneous tissue (Stevens), and the skin (Schmidt, Bramwell, Hitschmann).

The bone-marrow of the long bones was the seat of chloroma in seven cases (Schmidt, Paviot and Gallois, Paviot and Fayolle, Rosenblath, Dunlop, Trevithick, Dock and Warthin), in several of which the flat and short bones were involved. In six other cases (Rosenblath II, Bramwell, Gümbel, Weinberger, Sternberg, Türk) the fatty marrow was altered, either red or grayish-red. In some cases both kinds of change were present. In some cases the bones were not examined, in some others the examination was limited to a few bones, and inasmuch

as the affection of the bone marrow is not always symmetrical we cannot be sure that in the cases with negative results there were no green foci at all in the marrow.

Of the associated changes it is not necessary to mention any except tuberculosis. This was found in the lymph glands in the cases of Schmidt, Rosenblath I, II, and Koerner. In the latter Lubarsch found tubercle bacilli in the faucial tonsil and several enlarged glands in the neck.

Clinical Features. Most of the cases reported since 1893 show a general resemblance to the typical cases in the earlier series. Among 18 cases in which the clinical histories are given, early weakness was noted in 9, pallor or anemia in 11, exophthalmus in 11, swelling and eversion of the lids in another, deafness in 10, swelling of the temporal region in 9, swelling of the face in 3 more, enlarged lymph glands in 8, emaciation in 6, rapid pulse in 6. Pain was often a prominent symptom, and was most often felt in the head, eyes, teeth, or ears, or in the hips or legs. Hemorrhages in the skin or mucous membranes were noted in 8 cases. Blindness occurred four times. The liver was enlarged in 3, the spleen in 7 cases. Albumose (Bence-Jones) was present in Weinberger's case. In both of Rosenblath's it was absent. In other cases there are no evidences for or against. It is noteworthy that in the 3 cases cited the bone-marrow was altered.

Some of the cases require more detailed reference.

In Lang's case, a man, aged fifty-two years, was seized with violent pain in the head and teeth three months before admission. At the same time a hard tumor appeared on the right cheek, with obstruction of the nares and pain in the right eye, with exophthalmus and blindness.

The tumor became adherent to the skin, and ulcerated in the center. It projected into the palatine vault and the nose. It was removed by a resection of the maxillary bone, exposing a large cavity covered with green nodules, extending to the meninges. Owing to this the operation was not completed. The results were not known, as the patient disappeared.

In Bramwell's case the most remarkable feature was an eruption, beginning on the chest and spreading all over the body, consisting of flattened elevations from the size of a pinhead to that of a sixpence, often confluent. They were superficial, painless, and for the most part of a slaty gray color, sometimes yellow in the center. The gums were enormously swollen, firm and dark purple in color. The conjunctiva was infiltrated with a translucent, fleshy-colored growth. The eruption on the skin in time became yellow, yellowish-green, or distinctly green.

In Hitschmann's case there was also the combination of lesions in the mouth and skin. A man, aged twenty-six years, had a swelling of the cervical glands and enlarged spleen. The glands suppurated spontaneously, and showed no tendency to healing; the resulting ulcer had blue edges. The right tonsil was ulcerated. A bit removed from the margin showed a lymphosarcomatous structure. In two months after the beginning of the observation the tonsils and the mucosa of the pharynx, nasopharynx, fauces, and nares were greatly swollen. The blood was then normal. In two months more the skin became darker, of a pale-brown color, most intense over the cheeks and breast. A disseminated eruption appeared, with slightly elevated lesions, the size of lentils, of a grayish-green ("reseda") color, unchanged by pressure. The connective tissue of the eyelids became a pronounced grayish-green color; the scleræ also had a greenish tint. Other mucous membranes were pale-red, transparent, and finely nodular. Infiltrations formed in the soft palate, the base of the tongue, and upper part of the larynx. The tonsils were replaced by nodular tumors. There were large, hard, and almost immobile packets of lymphatic glands in the neck, axillæ, and inguinal regions. The bones were tender. There was remittent fever. The blood then showed relatively many large lymphocytes, later considerable lymphemia, with anemia, poikilocytes, polychromatophilia, and normoblasts. The patient died six months after admission. Grass-green new-growths were found in the tonsils, the mucosa of the gums, palate, nose, pharynx, larynx, and bronchi; in the cervical and mediastinal glands. The diagnosis of chloroma was made during life (1903), from the lesions in the skin.

In Schmidt's case there was a distinct green discoloration in the skin of the face and also on the body, but on the latter there were recent hemorrhages. There were also subcutaneous nodules.

The foregoing cases are interesting on account of the new features they add to the clinical picture of chloroma. It would increase too much the length of this paper to speak of the skin alterations in leucemia and allied conditions. Those especially interested will find a useful compilation in the monograph of Nékám,[1] while other interesting data are contained in the articles of G. Dieballa,[2] F. Pinkus,[3] and C. Audrey.[4]

In Gümbel's case there was transverse myelitis, due to pressure of the chloromatous masses upon the cord, and in Rosenblath's first case there was degeneration of the right posterior column of the cord in the lumbar and dorsal regions from pressure.

Sciatica was a marked symptom in the cases of Rosenblath, Harris and Moore, and Klein and Steinhaus.

In Trevithick's case tumors were discovered

4 Journal des maladies cutanées et syphilitiques, 1902.

in the breasts, in a girl aged thirteen years. The tumors became larger. "The left breast was composed of two very hard, globular tumors, each about the size of a hen's egg, freely movable over the deep parts, but adherent to the skin. The opposite breast was represented by three similar tumors." The mammary tumors "showed through the skin as being of a dark-blue color." The patient also presented the common features of pallor, proptosis, swelling in the temporal regions, subcutaneous hemorrhages, and nodules on the sternum and ribs. Post-mortem, growths of light-green color were found connected with various bones, in lymphatic glands, kidneys, liver, ovaries, pancreas, thyroid, dura mater, and in the choroid plexus of the lateral ventricles.

Dunlop's case was the first one in which a diagnosis was made during life. The patient, a boy aged five years, was fairly healthy up to a year before admission. For fully a year patches of ecchymosis were frequently noticed under the skin. In May, 1901, pallor was obvious, and for some months before that it was observed that any scratches on the body tended to suppurate. After a wetting and chill the boy became easily tired, called out in his sleep, and snored. His appetite was poor, and he grew steadily paler and more emaciated. In August his eyes became prominent, with dilated veins on the lids. In September he became deaf. On admission, September 30, 1901, he looked very ill, and was pale, with a waxy, yellow tint. There was a profuse petechial eruption everywhere except on the face, with two larger hemorrhages over the dorsal, spinal column, and the right knee, with a yellow discoloration, as of an old hemorrhage, on the right shin. Both eyeballs protruded, but the lids could be closed. There were a few enlarged glands under the jaw, on both sides, and in the posterior triangles of the neck and the groins. The heart dulness was enlarged; there were loud hemic bruits; pulse 110, irregular in time and force. The liver and spleen were not enlarged. The urine contained a small amount of albumin. The blood: hemoglobin, 32 per cent.; red blood corpuscles, 1,800,000; leucocytes, 24,500. Lymphocytes, large preponderating, 73 per cent.; polymorphonuclears, 17 per cent.; myelocytes, 5 per cent; unclassified, resembling myelocytes, 5 per cent. A few nucleated reds.

The eyes became more prominent, the deafness worse. In the mouth a hard, purple swelling appeared on the hard palate, extending nearly the whole anteroposterior extent from the teeth nearly to the median line, with discoloration to the median line. A similar smaller swelling appeared on the lower jaw on the right side, external to the teeth. In October a smooth, rounded swelling appeared in each temporal region, reaching behind to about half an inch in front of the pinna, and in front of the outer edge of the orbit, and apparently continuing into the orbit. On October 22 the diagnosis of chloroma was made. Photophobia came on. The upper eyelids became infiltrated, especially in their outer halves, with firm, smooth swellings which seemed to proceed from under the roof of the orbit in the region of the lacrimal gland, and extend to the margin of the tarsal cartilage. In the left lower eyelid there was a tumor extending from canthus to canthus, appearing to come from under the lower margin of the orbit. The retinal veins were tortuous and moderately distended. In the right eye there was a minute extravasation of blood near the disk, and exudation into the disk and retina in both eyes. The leucocytes increased to 68,000 by November 2. A pale, greenish-yellow tumor of jelly-like consistence made its appearance at the inner canthus of the right eye, and gradually advanced over the eyeball, covering its lower half. There was a smaller similar tumor in the left eye. Frontal pain became intense; the temperature rose to 101° F., the pulse to 140. The temporal tumors seemed to become smaller. Marked optic neuritis, with linear hemorrhages, developed in the right eye, still more marked optic neuritis in the left eye. By November 12 the tumors on the eyes covered both eyeballs. The corneæ were apparently destroyed. The temporal tumors were smaller. Leucocytes, 107,000; red blood corpuscles, 815,000; hemoglobin, 12 per cent. On November 15 the eyeballs were less prominent, leucocytes 123,000, waxy pallor of face and engorgement of veins striking, sordes on lips and teeth. After coffee-ground vomiting the boy died on November 16.

The cases of chloroma with tumors of the orbit have close clinical relations with other orbital tumors, and often result in sending the patient to an ophthalmologist. But the orbital tumors do not suffice to make the diagnosis of chloroma. Besides leucemia without chloroma, lymphosarcoma, and other formations often affect the orbits, causing exophthalmus in some cases. One of us (Dock) has had an opportunity of seeing a number of these cases clinically in the service of Prof. Fleming Carrow. The most interesting one is still under observation. Examination of an excised portion by Dr. Warthin, shows a lymphomatous structure. In addition to the orbital tumors there are growths in various parts of the body, including the roof of the mouth. The leucocytes number 10,000, 40 per cent. being lymphocytes, seven per cent. eosinophiles, but without the finer details of lymphatic leucemia. Risel has given a useful *résumé* of the literature of this part of the subject.

The cases without swellings in the orbit and temporal region are of special interest in connection with the one now reported. In Weinberger's case, a boy, aged fifteen years, had rigidity of the skin and weakness of the lower extremities, following scarlet fever. The cervical and inguinal lymph glands became enlarged; there were hemorrhages from the nose and gums and in the skin, hemorrhage from the right ear, deafness, splenic tumor, dilatation of the heart, and fever.

The urine contained Bence-Jones albumose. The growths involved the lymphatic tissue almost universally, the dura and serous membranes, the liver and kidneys, and the periosteum of the vertebræ. The tumors penetrated the vertebral canal and compressed the cord.

In Sternberg's case, too, the skull was not involved, but all the superficial and deep lymphatics, especially those of the floor of the mouth, were affected. The patient died of intercurrent disease (putrid bronchitis as the result of the perforation of a softened anthracotic bronchial gland into the esophagus and bronchus), so that the case really presents an early stage of the disease and seems to bear out the author's belief of a primary focus in the soft palate and pharynx.

A marked tendency to deafness and other ear symptoms were shown by the later cases, as in the earlier ones. One of the most striking examples was shown by the patient of Koerner. A boy, aged six years, became deaf. He also had headache and double exophthalmus. Both abducent nerves were paralyzed, the cutaneous veins of the forehead distended; both temporal regions were swollen. There was choked disk. The tympanic membranes bulged; they were pale grayish-yellow. The left mastoid was tender, but not swollen. Considerable pus was evacuated from both tympanic cavities. The diagnosis was phlebitis and thrombosis of both cavernous sinuses. After a fresh puncture of the left tympanic membrane, with elevation of the temperature, a mastoid operation was performed. The patient collapsed, but revived, and the operation was finished without exposing the lateral sinus. Death occurred five weeks later, without rise of temperature, but with frequent pulse (144) and respiration (66), and with rigidity of the neck. Post-mortem, no phlebitis was found, but instead a marked chloromatous growth involving the sinuses, the base of the skull, and other parts. Koerner analyzed the ear conditions in all the (20) cases of chloroma available, with great thoroughness, and found ear symptoms in ten.

The literature of the ear complications in leucemia has grown considerably since I referred to it in my former paper. For recent cases see Kast,[1] Kümmel,[2] Schwabach.[3]

Out of the protean symptoms of chloroma cases we can separate three sets of conditions: the mechanical results of the green growths, causing many symptoms, both objective and subjective, (exophthalmus, visible tumors, pain, deafness, etc.); the toxic symptoms, as weakness, fever, emaciation; and the blood symptoms, such as pallor, hemorrhages, and alterations of the blood itself.

The latter requires more particular consideration, and more especially so because of the effort I made in my previous article to show a relation between chloroma and leucemia. I need only allude to the resemblance of many of the symptoms of chloroma to those of leucemia, especially of acute leucemia. The condition of the blood, however, is the criterion of the leucemia change, and its condition in chloroma cases requires more detailed examination.

The Condition of the Blood. Ever since Recklinghausen assigned chloroma to the leucemic group of diseases the blood has been the most important single clinical feature, but owing to the imperfect application of blood examinations in general, and failure to appreciate the nature of cases during life, the blood has not yet received as much attention in chloroma as it deserves. In five of the present series of cases the blood was not examined (Lang, Koerner, Paviot and Gallois,[1] Harris and Moore, Hichens). In two it was not fully examined, or, at all events, not fully reported. In one of these—Schmidt—it is said the blood showed simple anemia; in the other (Paviot and Fayolle) there was said to have been leucocythemia of one to three or four. This latter statement is not as definite as that of Ayres, who described leucocytosis in his case without increase of "small lymphocytes and those white cells characteristic of splenic and myelogenic leucemia." More prolonged examinations might have modified the descriptions in both cases. In Türk's case there was leucopenia with severe anemia. In the other thirteen cases the conditions were more characteristic of leucemia, though in one the leucocytes were not increased. This was the case of Bramwell, in which there were 8,000 leucocytes per c.mm., with 95 per cent. of lymphocytes, "chiefly large lymphocytes, with large nuclei and clear, non-granular protoplasm. During the month the patient remained in the hospital the blood condition remained practically the same." As Bramwell remarks, "the mere fact that the leucocytes were not increased did not exclude leucemia." In ten cases, according to the reporters, the blood resembled that of acute leucemia or acute lymphocythemia.

Examining these cases in detail we find in Rosenblath's first case: red blood corpuscles, 1,000,000; leucocytes, 300,000. "The small mononuclear lymphocytes appear in small numbers, and the polymorphonuclear neutrophiles are scanty in proportion to mononuclear forms of various sizes, the smallest of which only slightly exceed the red corpuscles, the largest reach a considerable size. The protoplasm is usually reduced to a narrow ring, the outer layer of which often stains deeply with methylene blue. Only in the large forms has the protoplasm a greater extent. The nucleus stains rather faintly, shows usually a granular or filamentous network, is round or oval, usually simple, but sometimes double. There is moderate poikilocytosis, only an occasional nucleated red corpuscle." In

1 Deutsche med. Wochenschrift, 1894, Beilage 27, p. 187.

1 Paviot and Gallois are of course in error when they intimate that the blood had not been examined in any of the cases before their own.

Rosenblath's second case the red corpuscles varied from 3,700,000 to 2,300,000, the leucocytes, 40,000 to 58,000; later to 37,000. There was distinct poikilocytosis, a nucleated red cell, usually a normoblast, in almost every preparation. The leucocytes resembled those in the first case. The polymorphonuclear neutrophiles were considerable at first, but later were reduced to one-quarter or one-fifth of all leucocytes. Small lymphocytes were scanty, eosinophiles very rare. Sutherland's case (observed in 1893) had 2,200,000 red corpuscles. The leucocytes a few hours before death were "180 to a field. There was a great increase of lymphocytes, varying in size." In Stevens' case the blood count was: red corpuscles, 766,000; leucocytes, 491,600; hemoglobin, 15 per cent.; small lymphocytes, 94.6; large lymphocytes, 1.4; polynuclears, 2.7; eosinophiles, 1.3. In Gümbel's case the condition of the blood during life is not reported. Post mortem, the red and white corpuscles after sedimentation were about equal. "The great majority of the leucocytes belong to the group of large lymphocytes (Ehrlich); the rest are small lymphocytes. There are two kinds of the former. In one, two or three times as large as a red corpuscle, there is a large nucleus and, as a rule, little non-granular protoplasm. The nucleus is usually vesicular, only the nuclear membrane and chromatin network stain intensely, but some forms occur in which the whole nucleus takes blue intensely. The nucleus is usually oval and excentric, but not rarely is indented, so that it has a saddlebag form. Less frequent are cells of the same size, but with a pale, indistinctly outlined nucleus, usually resembling a shadow, and often not possible to recognize. This is the form represented by Dock as A. Fig. B. Polymorphonuclear cells are rare, also eosinophiles, and these have nuclei like those of the lymphocytes described." Normoblasts, megaloblasts, and Charcot's crystals were not found in the blood.

I have not been able to find the full report of the blood in Sternberg's case, which was to have been published in detail by Obermayer. In another place[1] Sternberg mentions it as giving the picture of acute (large celled) lymphatic leucemia. In Weinberger's case the red corpuscles ranged from 4,500,000 to 3,200,000; leucocytes, 13,000 to 72,000. In the beginning there were 86 per cent. of large lymphocytes, few polynuclears and eosinophiles, no mast-cells. With 72,000 leucocytes the large lymphocytes were still in the majority. "The blood was in all respects like that of acute leucemia. In Trevithick's case there was extreme anemia, but no count was made. "The blood was first examined three weeks before death. There was then great increase of white cells. . . . On comparing the films made at that time with those prepared shortly before death it was evident that the number of white cells in the blood increased very rapidly. The change, in fact, resolved itself into an enormously great and rapid increase of mononuclear cells. Among this crowd of mononuclear cells, which in the later stages became approximately equal in number to that of the hemocytes, there appeared a considerable number of bodies which, after careful examination, I believed to be degenerating nuclei derived presumably from defunct cells. These bodies varied in size and shape, but in some cases their dimensions were surprisingly large, and I saw several that possessed a diameter equal to six times that of the neighboring red blood corpuscles." These bodies resembled some in a preparation from a case of acute leucemia. "Some of the intact mononuclear cells found in the blood attain exceedingly large dimensions. Great variation in size is noticeable, and they seem to be distributed in groups."

The illustration given in Trevithick's article shows many cells such as occur in our present case of chloroma, as well as in many cases of acute lymphocythemia, while the degenerated cells so clearly described by the author are such as occur in leucemias of various kinds, and were particularly marked in a case of chronic small-celled leucemia reported by Dock.[1] In Hitschmann's case the blood, late in the disease, contained "relatively many large lymphocytes, later considerable lymphemia, with anemia, poikilocytosis, polychromatophilia, and normoblasts." In our own case, while the blood shows some differences as compared with many cases of acute leucemia hitherto reported, it has probably many counterparts in the latter disease. In its eosinophile cells and myelocytes it differs from Dock's (1893) case and forms a transition from many of the other cases to those of Dunlop and Klein and Steinhaus. In Dunlop's case the blood at first showed: hemoglobin, 32 per cent.; red blood corpuscles, 1,800,000; leucocytes, 24,500. The differential count was: lymphocytes, large predominating, 73 per cent.; polymorphonuclear, 17 per cent.; myelocytes, 5 per cent.; unclassified and transitional forms resembling myelocytes, 5 per cent.; a few uncleated red cells. The red cells fell in six weeks to 815,000; hemoglobin, 12 per cent.; the leucocytes rose in the same time to 123,000. Dr. J. S. Fowler has described the blood in this case,[2] and has given a somewhat different count. For example: October 5, leucocytes, 25,000; small lymphocytes, 15; large, 48.5; polynuclear, 31.5; eosinophiles, few; myelocytes, 5. November 11, leucocytes, 64,000 (Dunlop gives the number November 12, as 107,000); small lymphocytes, 15.5; large lymphocytes, 53.5; polynuclear, 16; myelocytes, 15; no eosinophiles in the last two counts two weeks apart. Divergences in leucocyte counts in different observers are, of course, very common, depending partly on staining technic, partly on different conceptions of certain cells, but the discrepancy in the

1 Verhandlungen des Deutschen patholog. Gesellschaft, 6 Tagung, 1903, pp. 30-33.

1 Moscow International Medical Congress, University Medical Magazine, March, 1898.

2 International Clinics, 1903, series 13, vol. iii, p. 225.

polynuclear counts in this case is hard to understand. Nevertheless, we can accept the reports as showing a still more distinct transition toward myelocythemia than was present in our own case.

A still greater departure from the lymphocythemic type was present in the case of Klein and Steinhaus. Here the leucocytes rose from 20,000 to 41,000. Lymphocytes varied from 40 per cent. small, 10 per cent. large, to 19 per cent. small, 47 per cent. large. Myelocytes varied between 16 and 32 per cent. The report does not describe the rest of the cells, but it is obvious that the case was not an ordinary one of mixed-celled leucemia, as the authors seem to intimate. A more distinct example of the latter occurred in a case of Türk's,[1] which I have excluded from the list of chloroma cases for the same reasons that made me exclude some other probable cases reported under the title of leucemia. In this case, a man, aged thirty-eight years, had hemorrhages from the gums, weakness, anemia, ecchymosis in the retina, enlarged spleen, and pain in the sternum. The blood examination showed: red corpuscles, 1,600,000; leucocytes, 42,000; hemoglobin, 19. Differential count: 14.75 lymphocytes, 32 polynuclear, 47 myelocytes, a few eosinophile myelocytes, no mast-cells. In seven days the blood fell to red corpuscles, 500,000; leucocytes, 58,000; hemoglobin + 10; lymphocytes, 18; polynuclears, 37; myelocytes, 37; 1 normoblast. Post mortem, there was diffuse grass-green infiltration in the bone-marrow of the vertebræ, ribs, sternum, and proximal ends of both femurs. The upper part of one humerus had reddish-gray marrow, the other long bones fatty marrow. The retroperitoneal glands were green. Here we miss the full picture of mixed-celled leucemia, especially eosinophile and mast-cells, normoblasts, and megaloblasts. But the case has an important bearing on the question of the nature of chloroma that must be considered in another connection, and illustrates the diversity of blood pictures in leucemia, which is suggested in the relatively small number of cases of chloroma. Investigations by many observers are putting it beyond question that besides the two main groups of leucemia there are many varieties, as I have held for many years. The exhaustive and authoritative article of Dr. A. O. J. Kelly, presented a year ago, makes unnecessary a repetition of the evidences now at hand.

While it is obvious that in many cases of chloroma the blood resembles that of acute leucemia, and while the symptoms are often acute, we need more exact observations. The blood examinations, as a rule, were not made early enough to determine this fact—a difficulty that occurs sometimes in non-chloromatous "acute" leucemia. There are a few interesting observations already available in chloroma. In Rosenblath's first case there were 300,000 leucocytes at the first examination, three and one-half months after the beginning of symptoms. In the second case of the same author the blood was first examined eleven days after the first symptoms, and contained 40,000 leucocytes per c.mm., increasing in eight days to 58,000, but in two months the number was lower—37,000. The patient died ten days later. In Weinberger's case the leucocytes rose from 20,000 to 72,000 in two days. In Dunlop's case they increased from 24,500 to 123,000 in six weeks. In this case petechiæ occurred early, suggesting an alteration of the blood. In our own case the symptoms indicate an anemia very early. It is impossible to tell what changes the blood passed through, but the extreme oligemia suggests grave failure of the red blood-forming organs, which might have been due to the overgrowth of the normal tissue by the morbid process, which sooner or later produced the excess of leucocytes in the peripheral blood. There was no distinct change in the number of leucocytes under observation, and it is, of course, as possible that leucocytes were more numerous at some previous period as that they rose just before the end.

From the data now available the relationship of chloroma to leucemia seems settled. That the full picture of leucemia does not always develop in all cases is to be expected. That qualitative changes will occur in the blood, and that quantitative changes appear in regard to certain common cell forms, there can be little doubt. But assigning chloroma to leucemia of course leaves many problems unsettled. One of the first questions that arises in this connection is with reference to lymphocytosis in so-called lymphosarcoma and other diseases not yet positively identified with leucemia, but with many indications of relationship. This, as well as some other questions, can only be determined by the discovery of the etiologic factors, though careful clinical observation and study of the blood may materially further the subject before that consummation has been reached.

Two other questions raised by chloroma require some attention: the nature of the color and the histologic position of the new growth.

The Color of Chloroma.—The later cases of chloroma have not advanced our knowledge of the nature and cause of the green color. No extensive examination seems to have been made, probably because the most obvious explanations had been tried and been found wanting in the earlier cases, where the ordinary chemical and physical methods were applied for the detection of possible color principles. There is apparently a difference in behavior of the color under comparatively simple conditions. Most observers state that the color fades quickly on exposure to the air (or light), as during the autopsy; but Dr. Warthin noticed an increase in the depth of the color in our last case, possibly from drying. Almost all say the color fades in various preserving solutions, and does not go into solution in the fluids. Risel, for example, found that the color was not preserved in Kaiserling's method, in

1 Wiener klin. Wochenschrift, 1903, p. 333.

which the greenish color of tuberculous foci in the same specimens retained their peculiar tint. Alt found that the tissues retained their dark grass-green color in formol solution, and the fluid itself was of a dirty-green color and looked fatty. Allowing the fluid to evaporate, large droplets of dark-green, oily substance remained, with many octahedric crystals, like calcium oxalate. The account suggests bile coloring matter, but no mention of jaundice is made.

That the color is not a post mortem phenomenon appears from some observations during life in the older series, as well as those of Lang, Bramwell, and Hitschmann in the present one. On the other hand, an origin from broken-down blood pigment is suggested by certain observations. Risel found hemosiderin granules in the tumors, and referred these to breaking down of red blood corpuscles, but he ascribed the green color not to these granules, but to some other substance of hematogenous origin. He compared the process to the "green granular pigment" found in the dog's placenta, explained by Lieberkühn and Strahl as originating in extravasated blood. Lubarsch found the color a deeper green along the sinuses in his case—"in fact, a diffuse green coloration of the sinus walls was observed in the vicinity of the chloromatous tissue." Of course this does not prove that the blood made the green color, any more than that a pigment of some other origin was deposited in those parts. Gümbel[1] quotes some experiments of H. Rücker on blood pigments, to which he might have added some other suggestive experiments, cited in the same thesis, showing the possibility of deriving green coloring from blood. This, of course, follows from the changes in subcutaneous hemorrhages, and the observations on such processes by Langhans and others.

Risel, Lubarsch, and Weinberger made it practically certain the color is not of bacterial origin, while Lubarsch was unable to find pigment granules in either sections or fresh preparations. Sternberg's results with Sudan III, showing fat droplets in the lymphocytes, does not prove that the color is due to an ordinary fat.

Paviot and Gallois made some tests of chloroma tissue with guaiac, which led them to the conclusion that chloroma contains an oxidizing diastase. They also found, however, that a similar reaction occurred with other tissues of rapid growth, confirming the conclusion of Klein that the reaction depends on the relative youth of the cells. The suggestion of Schmidt that the color is due to the shape of the cells has not found any confirmation.

Bramwell raised the question whether the color is due to the same causes in all cases of chloroma. He considered it possible that it might be due to different causes in different cases, and that it might even be due to different pathological conditions. He also thought there might be cases of chloroma without green tumors and no green lesions; "that the green discolorations, though they had hitherto been considered to be essential and characteristic features of the disease, might, in some undoubted cases of chloroma, be absent." These suggestions are not as paradoxical as they seem. They show the danger of making such a feature as color the basis of classification, especially when pertinent cases are few and the color itself is so elusive and so difficult to analyze as in chloroma. It is true that in order to deserve the term chloroma there should be a green color, but if the green color is associated with a definite structure it might be possible to make the diagnosis even if the color were absent, either naturally or as the result of preserving methods. To take a clinical example, not every chlorotic has a greenish tint, as Virchow pointed out long ago. In a number of recent cases there were new growths of ordinary color besides the green ones, as there were in some of the old ones (*e.g.*, Dock, 1893). In Schmidt's case some lymph glands showing the structure of malignant lymphoma were removed eight months before death, and showed no trace of green color.

In Körner's case some of the tumors were not green, though they had the same structure as the green ones. This was also true in Weinberger's case, and in a case of acute leucemia Bramwell found a few green lymph glands. It is therefore certain that the green color is not present in all the lesions in chloroma, and possibly that it is not present in the beginning. That the color occurs in other processes appears from the cases of Klein and Steinhaus and Türk, the earlier cases of leucemia with green lesions being left out of consideration because of a certain imperfection in the blood examinations. But the various observations of pure lymphocythemic chloroma and the two cases just mentioned, make it certain that whatever the green color is due to, it is not confined to any one particular histologic structure.

It is interesting to note that in Trevithick's case the heart clot was green, but less so than the new growths. In Gümbel's case the sedimented leucocytes were green, and there were greenish clots in the heart, but in many other cases, including Rosenblath's with 300,000 leucocytes, green clots are not mentioned.

VIEWS OF AUTHORS ON THE CLASSIFICATION OF CHLOROMA.

Most authors agree upon the main histological details of chloroma. There are certain differences regarding the size of the cells that make up the growths, some describing them as small, others large, others even as very large, but this difference is probably chiefly a matter of standards. On the other hand the interpretation of the structure is not always the same. It will be interesting to pass some of the explanations in review.

Lang made a variation when he described

[1] Zur Kenntniss des Hämatoporphyrin und seiner Derivate. Inaug. Dissert., Strassburg, 1901.

the growth in his case as a myxosarcoma, or chloromyxosarcoma. I see no reason, however, from excluding it from the statistics of chloroma, as I did in the case of Bock in the earlier series.

Schmidt thought the process, like that in leucemia and pseudoleucemia, primarily affected the lymphatic apparatus and the closely related bone-marrow. He thought the disease was without metastases.

Lubarsch thought the tumors so much like lymphoma and lymphosarcoma, histologically, that but for their green color the possibility of anything but lymphoma would never have been entertained. But he would separate chloroma, as well as lymphosarcoma and tumors of that kind, which seem to have a toxic or infectious origin, from sarcoma and other autogenous tumors. "The former are merely a manifestation of a general diseased condition of the organism. Though they may develop in large numbers in the body, each tumor must be looked upon as a primary condition and not as a metastatic formation depending on the dissemination of some primary autogenous growth; while they usually have a predilection for lymphoid tissue, they have been found in other parts of the body." Lubarsch, like most recent authors, agrees that Dock was right in emphasizing the differences between ordinary periosteal sarcoma and chloroma.

Paltauf,[1] who discussed the subject in 1897, placed chloroma, with leucemia, pseudoleucemia, and myeloma, among the lymphomata or lymphosarcomata in the sense of Kundrat, and more definitely under lymphosarcoma as an appendix, and he suggested that it should not be spoken of as a sacroma. Since the view of Kundrat has strongly influenced many in their opinions, and yet has not been universally accepted, it may be well to explain that author's conception of lymphosarcoma.[2] According to Kundrat, lymphosarcoma arises from lymph glands or from the follicles of a mucous membrane, always from a group of follicles; and though it may long remain localized there, it in time passes into other lymph glands or follicles, breaking through the capsule and infiltrating the surrounding tissue. The infiltration proceeds more or less rapidly according to the tissue affected, most rapidly in loose tissue, under the surface, on and in mucous membranes and serous membranes, so that in hollow organs large areas are involved, but usually not leading to stricture, rather to dilatation. Distant locations are involved, somewhat resembling metastasis in other tumors, but never causing nodules, rather infiltrations. One reason why Kundrat rejected the idea of metastasis is that the usual seats of metastatic cancers and sarcomata are not affected,—that is, the internal organs—but rather the intestinal canal. Metastases by way of the blood circulation rarely occur, also ruptures into bloodvessels; the latter are more likely to be compressed and obstructed. However, secondary thrombi occur. Unlike leucemia and pseudoleucemia, lymphosarcoma does not have diffuse infiltrations of the liver and spleen. These organs are more likely to be small, in consequence of marasmus. The bone-marrow is also not affected.

MEDICAL PROGRESS.

PHYSIOLOGY.

The Effect of Formaldehyde and Calcium Chloride on the Hemolytic Power of Serum.—Since it has been shown that the hemolytic power of foreign serum may be destroyed or attenuated in vitro by the addition of small quantities of formaldehyde, calcium chloride and other substances, C. C. GUTHRIE (*Am. Jour. Physiol.*, September 1, 1904) thought it of interest to investigate the effect of the intravenous injection of formaldehyde and calcium chloride. Certain preliminary experiments were performed with the following results: Slight variations in both the rate of hemolytic activity, and the total hemolytic power of serum of different animals of the same species (dogs), for washed rabbit's corpuscles were observed. Age, sex, weight, nutrition, breed and pregnancy appeared to have but little or no influence in the hemolytic action of the serum. Hemorrhage, asphyxia and excess of anesthetic (ether) have little or no effect in the hemolytic action of the serum; nor has the subjecting of dog's serum to a temperature of 5° to 10° C. for seventeen hours and then thawing. The injection of formaldehyde causes a moderate though decided decrease in the hemolytic power of the serum. The decrease is most marked in the serum from blood drawn immediately after the injection is finished, the hemolytic power of the serum gradually approaching normal after the initial inhibition, which is abrupt. Calcium chloride produces the same effect, except that the inhibition of hemolytic power is greater for calcium chloride in the proportions injected for formaldehyde.

The Reducing Action of the Animal Organism under the Influence of Cold.—The application of intravital staining methods to the study of this problem was made by C. A. HERTER (*Am. Jour. Physiol.*, September 1, 1904). If a living rabbit is infused with a solution of methylene blue, one notes during life and after death a variability in the reducing power of the different kinds of cells. The lungs, liver, suprarenals and gray matter of the central nervous system reduce methylene blue to its colorless leuco-base during life. The muscles, spleen, kidneys, and connective tissues reduce less actively. After a rabbit has been cooled by means of cold wet cloths, the intravenous infusions were made into the jugular vein. An inspection of the pectoral muscles showed that they were blue in color. The muscles of the control animal were likewise blued, but the coloration was less than in the cold animal. After the close of the infusion, the blue present in the muscles of the normal animal is gradually reduced to leuco-methylene blue, whereas the reduction is distinctly slower than in the case of the cooled rabbit. On exposure to the air or after treatment with oxidizing agents there is a return of color in the muscles of the normal animals, which indicates that the differences in color are due chiefly, if not wholly, to differences in the power of reduc-

tion, and not largely to the transportation of the dye. Cold causes a marked lessening in the reducing activity of the gray substance of the brain, cerebellum and other central nervous organs. The author emphasizes the following conclusion: A considerable fall in body temperature is attended by a diminished reduction of methylene blue to leuco-methylene blue, and this result is particularly striking and unequivocal in the case of the muscles (including the heart and diaphragm) and the gray substance of the central nervous system.

The Elimination of Endogenous Uric Acid.—The uric acid eliminated by the organism has two sources: (1) food containing purin bodies, such as meat, and (2) the disintegrating cells of the body. The uric acid originating in the former is known as exogenous, while that originating in the latter is termed endogenous uric acid. E. W. ROCKWOOD (*Am. Jour. Physiol.*, September 1, 1904) conducted a series of experiments in order to verify the conclusions of Burian and Schur, namely, that the endogenous output is variable for different individuals, but constant in quantity for the same person. He found this to be the case; there is a marked individual factor in the output of uric acid on a purin-free diet. This varied far less than either the elimination of nitrogen or of phosphoric acid. The relative individual constancy is the more striking in view of the marked difference in the composition of the diets at different periods. The importance of the individual factor in contrast with the dietetic factor is seen in the comparison between the output of different persons living on precisely the same diet. A considerable increase in bodily exercise does not affect the uric acid output noticeably. In children, in proportion to body weight, the amount of endogenous uric acid eliminated is about the same as in adults.

Action of Depressor Nerve.—Since the opinions as to the real function of the depressor nerve are still divided, C. HIRSCH and E. STADLER (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 3 and 4) have attempted to solve the problem with a number of interesting experiments. When the nerves were divided a short increase in pressure invariably followed, but this is sometimes preceded by a short stage of lowered pressure, probably due to initial irritation of the nerve. The results are no different if the animal was first curarized, or if the aortic valves were so injured as to bring about an insufficiency or where an artificial stenosis of the aorta was created. Increased viscosity of the blood or artificial plethora were without any influence. It is probable that the depressor nerve exercises its function merely upon the first part of the aorta, preserving a certain amount of tonic spasm, so as to prevent overdilatation with increased blood pressure.

The Fate of Strychnine in the Rabbit's Intestine.—It was recently reported by Salant that the contents of the cecum of rabbits are capable of destroying strychnine. R. W. HATCHER (*Am. Jour. Physiol.*, October 1, 1904), finds that this is not the case; that strychnine, after having been mixed with the cecal contents, may still be detected, though with difficulty, and that this difficulty is to be ascribed to the formation of compounds of strychnine with organic constituents of the intestinal contents.

The Physical Relation of Chloroform to Blood.—Conclusions which are substantially identical with that arrived at by Moore and Roaf, are drawn by A. D. WALLER (*Proc. Royal Soc.*, July 19, 1904) from his recent researches on the above subject. They are that the absorption of chloroform vapor is greater by blood than by saline, and that blood acts as a special carrier of chloroform to the tissues just as it acts as oxygen carrier. The combination which certainly takes place between chloroform and protoplasm may possibly be accounted for on the lipoid theory (the union of chloroform and "lipoids"). The question whether chloroform can combine with all protoplasm indifferently or with its fatty constituents (lecithin, cholesterin) more particularly, is a subsidiary issue, in respect of which the above observations contain no decisive evidence. On the one hand, is to be seen the fact that all protoplasm is subject to the influence of chloroform, and on the other hand the fact that all protoplasm is associated with fatty constituents of which lecithin is the most universal representative. Lecithin is widely distributed in vegetable as well as in animal protoplasm; it is present in blood serum, which, as shown by Moore and Roaf, has a solvent power toward chloroform not far short of that possessed by blood.

The Function of the Cecum and Appendix.—The cecal appendages do not exist in fish, batrachians and reptiles, the small and large intestine forming a continuous tube. WILLIAM MACEWEN, in a voluminous paper (*Lancet*, October 8, 1904) states that the digestion in carnivorous birds and animals takes place principally in the stomach and the small intestine. The ceca being rudimentary or absent, while in the herbivora, the cecum is enormously developed and in the solipeds, it is the chief digestive organ, the stomach occupying a secondary place. Man, if not an omnivorous animal, is at least a carnivorous and herbivorous one. Therefore, one would expect him to possess, as he does, not only a stomach and small intestines, but also a cecum; the cecum being concerned largely with the digestion of vegetable food, and as this type of foodstuff consumed by man is of the most tender variety the cecum is of only moderate size. It is an interesting fact that in at least one patient the loss by operation of the cecum, iliocolic valve and a large portion of the ascending colon was necessitated by infection of the part, an obstinate diarrhea, which occurred without any apparent cause, seemed to have a very definite relation to the excision. As to the nervous mechanism of the appendix, although it is regarded as a mere diverticulum of the cecum, nevertheles both its nervous and vascular supply is more related to that of the small intestine than of the colon. Inasmuch as the circular muscles of the cecum are continuous with those of the appendix and the longitudinal cecal bands end on the appendix, it is not difficult to understand that the nervous mechanism of the appendix may initiate the larger movements of the cecum by first inducing movements in the appendix. Undoubtedly the appendix is subject to the same cerebral government, so far as its motions go as the small intestine. In the cecum and appendix, the glands of Lieberkühn are very numerous and well developed. In fact, they are packed so closely together that no room is left for absorption purposes. This in itself seems to point to the cecum and appendix, having a more purely digestive than an absorbing function. The succus entericus in the small intestines is of great importance in furthering digestion, it being well known that the proteolytic function of the pancreas is particularly favored by it. Pawlow considers it to be a ferment of other ferments, which he names enterokinase. Succus entericus, however, is not the only agent at work in the disintegration of a cecal pabulum. Micro-organisms undoubtedly play a very important part in disin-

tegrating by their metabolic processes many substances which have resisted the action of body digestants. Bizzozero has shown that the cells of the appendix in healthy rabbits contain enormous numbers of degenerative micro-organisms. Apparently the cells of the solitary follicles of the appendix have a controlling action on these organisms, and it is not unlikely that one of the appendicular functions may be to maintain cultures of these organisms to perform their functions upon the cecal fluids. It is, therefore, not unnatural that the determining factors in causing appendicular inflammation are usually of a digestive type. Deaver states that appropriate inquiry will elicit a history of such disturbances in almost all cases. Indeed, it is not improbable, because of the close relation between the appendix and the cecum through the superior mesenteric plexus, that a vast number of so-called cases of indigestion, which are heedlessly attributed to gastric disturbance, are in truth purely reflex manifestations of disturbed cecal and appendicular digestive functions. The author concludes that the mode of life, its hurry and its hygienic improprieties, are in a large part he cause of appendicular disease.

PATHOLOGY AND BACTERIOLOGY.

Lesions Produced by Tetanus Toxin.—The experiments of R. Odier (*Arch. de Méd. Expér.,* July, 1904) show that tetanine causes the degeneration and later the destruction of the motor end plates in the muscles. The axis cylinder of the nerves which convey the toxin are the seat of an anatomical degeneration proportional to the dose and the concentration of the toxin, as well as to the time which has elapsed since the introduction of the toxin into the organism.

Etiology of Macrocheilia.—For a long time it has been recognized that abnormal thickening of the lips can be brought about by two very different causes, viz., inflammatory reaction and the presence of neoplastic growth. Daniel Eisendrath (*Annals of Surgery,* September, 1904) states that the former cause is by far the more frequent. It is common in so-called scrofulous children, is very prone to relapse and is essentially of a chronic nature. It is associated with immense hypertrophy of the mucous gland, as well as of an increase of all the tissues which constitute the lip. Lymphangiomata have usually been considered to represent the type of tumor most frequently found. In this respect hypertrophy of the lips due to this cause is almost identical with macroglossia. The author's case, which is probably the second one on record, the first having been operated upon by Fränkel, has the following history: The patient was a young man, sixteen years of age, who suffered from a double ptosis as well as from a disfiguring thickening and protrusion of both lips. The anti-operative photograph presented shows the condition to have been extreme. His early history was negative. He was an only child and had always enjoyed good health. At the age of ten his parents began to notice a moderate thickening of the lips, which had continued uninterruptedly for six years. The physical examination of the parts showed that the skin covering the region was smooth. The lip was soft, not tender, and otherwise negative. Removal of as much of the tumor as possible was advocated, followed by a subsequent treatment with hot-water injections. The tumor was extremely vascular, and immediately on section a surprising number of little concretions, the size of a bird shot, streamed out of the wound. The author believed these little masses either to be small lipomata or simply normal fat. That this tentative diagnosis was erroneous became evident on microscopical examination. These tumors were seen to consist uniformly of glandular tissue precisely similar in type to that of the normal mucous gland of the lip.

Human Piroplasmosis.—The sporozoan parasite discovered by Donovan and classified by Laveran and Mesnil in the genus *Piroplasma,* is described, with an admirable colored illustration, and the history of the discovery of the parasite is given in a long article by C. Donovan (*Lancet,* September 10, 1904). He says that on June 17, 1903, he first found these organisms in splenic blood. In one year there were admitted to his wards seventy-two cases suffering from this disease, all of which were diagnosed by examination of blood from splenic punctures. Of this number, the death rate has been 30.55 per cent. The disease is exceedingly rare among Europeans, it being particularly prevalent in the dirtiest portion of the native quarter in the city of Madras. The sexes are equally amenable, and age is no bar to infection. Probably the reason that Europeans are so rarely infected is that they are usually well housed. The history of the discovery of the parasite was as follows: Donovan noticed that a great many cases passed through his wards which had many points in common with chronic malaria, and which, although registered as such, did not seem to the author to be true malaria on account of the absence from the peripheral blood of the usual parasite. In all these questionable cases the spleen was enlarged. Donovan believed that possibly the conditions might represent some hitherto unobserved stage in the malarial organism. With a view to determining this, he took smears of blood from the spleen post-mortem. He at once noted that the peculiar round and oval ring-like little bodies, which were characterized by two masses of chromatin situated on opposite poles, were different from anything ever before recognized as malarial hematozoa. He still believed, however, that he had discovered the long-sought-for resting-stage form of the malarial parasite. A splenic puncture during life proved that these curious bodies were not as Donovan had suspected they might be, post-mortem degenerations of splenic pus cells. It is most interesting to note that these piroplasms, when found in the peripheral blood, a matter of very rare occurrence, and only when the temperature ranges between 102° and 104° F., are of a very different form from that presented by the same parasite in the spleen. The number found in a single field will vary from one to thirty or more, although occasionally in well-marked cases even, great care has to be taken in finding the parasite. The number found, although varying with the amount of blood taken up in the syringe, does not appear to be in any wise dependent upon the severity of the disease nor upon the size of the spleen. Altogether Donovan has practised 110 punctures and has made this very interesting deduction from the series: One death unquestionably resulted from the simple operation. Puncture of the spleen of a fairly healthy man was made at 8 A.M. He seemed comfortable at three o'clock, when he was allowed to get up from bed. While going to get a drink of water he slipped and fell and was picked up dazed. Two hours later he died in extreme dyspnea. Post-mortem examination showed an extensive intraperitoneal hemorrhage. Calcium chloride has been ad-

minstered to all the cases since operated upon, and so far with apparent good results.

A New Color Reaction for Sugar.—A new test in which orcin is used is described by A. Neumann (*Berl. klin. Woch.*, October 10, 1904). He claims that this is not only a typical pentose reagent, but may also be used for the differentiation of other members of the group. The method is as follows: Ten drops of the watery solution to be tested are mixed with 5 c.c. of glacial acetic acid and a few drops of a five per cent. alcoholic solution of orcin. This mixture is brought to a boil, and then concentrated sulphuric acid added drop by drop. The test tube must be thoroughly shaken after every five to ten drops, otherwise the fluid will spurt from the tube. The acid is added until a distinct color appears after shaking. This depends on the concentration of the sugar solution, but even in weak solutions it becomes evident by the addition of from 40 to 50 drops. It is useless to add more than 50 drops, otherwise the orcin is decomposed and a yellow color appears. As soon as a distinct color appears, no further acid should be added, otherwise a mixture of colors results, or else the color becomes too deep for spectroscopic analysis. The fluid should be allowed to cool before determinations of color by the eye or the spectroscope are made. If the color is too deep, the addition of acetic acid will dilute the fluid without changing the color. The different varieties of sugar give the following colors: arabinose, violet red; xylose, when warm, a violet blue; when cold, blue; glycuronic acid, when warm, green; cold, greenish blue; glycose, brownish red; fructose, warm, brown; cold, yellowish brown. When the test is applied to diabetic urine, even in the presence of slight amounts of sugar, an intense brownish-red color appears, whereas in normal urine there results a pale brown and green tinge, which is probably due to the mixture of colors from traces of glycuronic acid and glycose.

Origin of Blood-Platelets.—By means of a special combination of eosin and methylene-blue, K. Priesich and P. Heim (*Virchow's Archiv*, Vol. 178, No. 1) were able to detect in blood-platelets a ground substance, filled with red granules and a surrounding rim of protoplasm which stains like the red cells. The red cells and less often the large mononuclear leucocytes, contain blood-platelets inclosed in their protoplasm. There are, however, distinct differences in staining between these included elements and the nuclei of the red cells. The position in centric or eccentric and sometimes the various stages of extrusion may be observed. Various experiments made to determine the nature of the substance of which the platelets were made up, proved that this was chiefly nuclein. If two ligatures are applied to a large vessel and the stagnating blood be examined after a certain time, the bodies are not increased in number, hence they probably occur as such in the circulating blood and do not precipitate out when the blood is at rest, as has been stated. Great importance has been attributed to the fact that if sublimate is allowed to act upon blood, structures resembling platelets are formed in great number from the red cells. These are not, however, true platelets, for they can also be obtained from the blood of chickens, which never contains platelets. The above facts together with the observation that animals whose red cell are normally nucleated, do not possess platelets, makes it very probable, that the latter are merely the degenerated and extruded nuclei. When the bone-marrow of young animals was examined, many nucleated red cells were found but among these was a large number whose nuclei stained like the platelets normally do, so that the various transition stages between both could be well studied. Both red cells and platelets are destroyed in the spleen, for if this organ be examined, large conglomerations can generally be discovered. The platelets are not indispensable for the clotting of blood but, as they are degenerated structures, they are the first to show those chemical changes which are necessary for the production of clotting.

The Formation of Glycuronic Acid in Man.—The results of a series of analyses of the urine in a case of acute cocaine poisoning made by J. Wohlgemuth (*Berl. klin. Woch.*, October 10, 1904) seem to explain the appearance of this substance. The patient had swallowed, by mistake, 0.75 gms. of cocaine, and was soon in a condition of extreme tachycardia and dyspnea. A gradual recovery took place in about two weeks. It was found that large quantities of phenoglycuronic acid were excreted, because as a result of the cocaine poisoning, the powers of oxidation were diminished and the body was unable to oxidize the sugar as it would have done normally, as well as the glycuronic acid due to the presence of the cocaine and the camphor which had been administered as a stimulant. A part of the sugar as well as the glycuronic acid entered the urine unchanged. The condition improved from day to day, as became evident from the gradual decrease of the sugar. As the glycuronic acid possesses a great affinity for the phenol, which under normal conditions enters into other compounds, it was excreted in the urine as phenolglycuronic acid. The case is interesting from the fact that it may throw some light on the hitherto obscure question of the primary origin of glycuronic acid.

Pulsating Gangrene of the Lung.—This is a morbid condition which has previously not been described. It is analogous to that rare affection pulsating empyema. John Lindsay Steven (*Lancet*, October 15, 1904) says that his case of pulsating gangrene is related to pulsating empyema only by the clinical fact of pulsation. There is a wide literature from prominent observers on this last disorder. West, McDonnell, Diculafoy, Comby, and others having contributed to the subject. A case of pulsating empyema occurred in a woman thirty-seven years of age. On inspection of the anterior chest, moderate fulness was evident from the level of the second space downward, so that no intercostal spaces were visible; percussion was everywhere normal, and the respiratory murmur was also unchanged. The general history and appearance seemed to point to an acute pneumonia. The patient developed hemoptasis, with a temperature of 103° F., which was markedly irregular and septic. The hemorrhages were continuous and the fetor of the breath marked. On autopsy the left lung was found to be firmly adherent from apex to base, projecting through the left aspect of the pericardium, a fluctuating swelling was found, bounded below by the diaphragm and internally by the adherent left lung. This was in a position to receive the systolic shock to the heart and was transmitted to the chest wall through the semifluid contents of the gangrenous cavity. The heart was neither hypertrophied nor fixed and the swelling and pulsation referred to was undoubtedly due to the peculiar fixation by adhesions of the lungs to the chest wall.

Carotid Body.—From the examination made by J. Funke (*Proc. of Path. Soc., Phila.,* September, 1904) it is not possible to believe that the carotid body is present as often as is generally maintained. Of the eight fetuses examined, it was present only once. A number of animals examined presented no such structure, and in one fetus a cervical ganglion occupied the position of the body. When present, the organ is enclosed in a vascular fibrous body from which bands penetrate into the interior, dividing the parenchyma into two halves. These halves are again separated into lobules, which are composed of cells having no definite arrangement. They are large, closely set, with abundant, poorly-staining protoplasm, and large, oval nuclei. Rarely they are separated by a delicate reticulum and exhibit gland-structure. An intimate relation with minute blood-vessels is everywhere evident. Tumors of the carotid body are rare, and generally occur in adolescence and adult life. In the fifteen cases reported, the youngest patient was eighteen years and the oldest sixty years. Neither sex seems predisposed. In two there was a family history of malignant disease. One of the tumors was first noticed after the extraction of a tooth and fracture of the inferior maxilla. This patient had a history of inflammation of the throat and glandular swelling. In another patient there was a history of tonsillitis. It is generally conceded that the body develops until the age of puberty, when it either atrophies or arrests in development. If the body continues to grow, a tumor is formed which generally belongs to the class of peritheliomata. These have been mistaken for tuberculous glands, liponia, sarcoma, aneurism or cyst of the neck and are generally malignant, since recurrence after extirpation has been reported.

Cause of Death After Double Nephrectomy.—If both kidneys are removed from a rabbit, the animal will remain alive for about a hundred hours in comparative good health. Death is usually preceded by paralysis of the hind limbs, and convulsions are rare. In order to determine the cause of death, H. Couvée (*Zeitsch. f. klin. Med.,* Vol. 54, Nos. 3 and 4) injected the blood and the blood serum of these rabbits into both healthy and nephrectomized animals, but no symptoms were noticed. The same negative results were obtained with the sterile extract of liver, kidneys, muscles and brain; in fact, it seems as if all these substances were harmless. Since the freezing point of the blood was considerably diminished in all cases, the author concludes that the real cause of death is the increased osmatic tension.

Bacteriological Study of the Throat in Scarlet Fever.—Streptococci and staphylococci were found by J. F. Schamberg and N. Gildersleeve (*Proc. of Path. Soc., Phila.,* September, 1904) in the vast majority of cases of scarlet fever, and the first mentioned organisms also frequently in apparently healthy throats. Both germs are undoubtedly often concerned in the complications of the disease, but are not to be looked upon as the specific agents. The diplococcus described by Class as the cause of the disease was found in but a comparatively small percentage. The interesting findings of Mallory of protozoa-like bodies will doubtlessly stimulate research along these lines. It is quite possible that the failure in the past to discover the contagium vivum of the disease, has been due to the fact that almost exclusive search for vegetable parasites has been made.

Pancreas in Diabetes.—The present knowledge of the relation of the pancreas to diabetes is summed up as follows by E. Sauerbeck (*Virchow's Archiv,* Vol. 177, supp.). In every normal body sugar metabolism is regulated by means of the liver, the nervous system and the pancreas. Changes in the liver may bring about hyperglycemia and glycosuria directly by an increased conversion of glycogen into glucose. The nervous system seems to have a stimulating, the pancreas an inhibitory effect upon this mechanism, since certain injuries to the brain and changes in the pancreas may lead to glycosuria. This latter organ exercises its influence upon the liver by means of an internal secretion, which is probably elaborated in the islands of Langerhans. These are highly vascular, and their characteristic cells stand in intimate relation to the vessels. Their specific nature is also evident from the fact that they resist many lesions which invade the parenchyma of the pancreas. It has been proven by experiment that diabetes will not occur as long as the islands are preserved. They present severe lesions (atrophy, hyaline changes) in almost all cases of diabetes, yet there is a certain percentage where liver, pancreas and nervous system are absolutely normal and only functional changes can be held responsible. The functional disturbance, however, may also reside in the brain or spinal cord. This theory of disturbed function without lesion applies especially to the hereditary forms of the disease in young individuals or in patients with marked symptoms of neurasthenia. By means of specific cytolysins it may be possible in the future to exclude one of the two components of the pancreas and thus to discover the true function of each.

OBSTETRICS AND GYNECOLOGY.

Heart and Circulation in Pregnancy and Puerperium.—The result of extensive clinical studies made before and after labor are published by A. Stengel and W. B. Stanton (*Univ. Penn. Med. Bull.,* September, 1904), and their conclusions may be summarized as follows: They believe that there is not during pregnancy any hypertrophy of the left ventricle nor special increase in its work. The increase in dulness toward the left is due to the upward displacement of the diaphragm and the consequent displacement of the heart in an upward and outward direction. The comparative outlines before and after labor, made from a series of tracings, show a rapid return to the normal position. A noteworthy fact was a frequency of the increase in the extension of dulness towards the left in the second and third interspaces and by the frequency of distinct pulsation in the same area. In the absence of any evidence of retraction of the lung, and in view of the fact that the pulsation discovered in this region was distinctly marked, it is evident that this condition of things is ascribable to distention of the conus arteriosus and root of the pulmonary artery. The frequent presence of a systolic murmur, most clearly audible in the same area, further substantiates this opinion. Moreover, the position of the right border of the heart seemed on the average too far toward the right, which, with the conditions present at the root of the pulmonary artery, convinced the authors that there is probably during the latter months of pregnancy some continuous dilatation of the right ventricle, though this is apparently of a very moderate degree. Such a state of affairs can hardly be regarded as surprising when it is remembered that the upward displacement of the diaphragm and pressure upon the lungs must necessarily increase the difficulties of the pulmonary circulation. The condition of the abdominal recti is important from the point of view of the circulation. In multiparæ separation of the recti materially lessens the tendency to displacement of

the diaphragm, and diminishes in a corresponding degree the displacement of the heart during pregnancy. After delivery this diastasis of the recti, however, may occasion a downward displacement of the heart, and the contrast before and after labor may be quite as pronounced as in primiparæ, though the first position occupied may not have been far from the normal. The investigations of the blood pressure show conclusively that there is no material increase of this pressure before or after labor. During labor a notable increase was sometimes found, similar to that observed by others.

On the Behavior of Leucocytes in Gynecological Diseases and Labor.—Whereas the value of a hyperleucocytosis in the presence of a hidden suppuration has lately been regarded as of lessened importance in surgery, it is claimed by Pankow (*Archiv f. Gyn.*, Vol. 73, No. 2) that careful observations have convinced him that it is of greater moment in gynecological diseases. In every case of inflammatory adnexal disease, if the leucocytes number more than 10,000, and all other causes for their increase can be eliminated, purulent inflammation of the adnexa is always present. But if the number is below 10,000, in chronic cases, suppuration cannot be excluded with certainty. The leucocyte count must always be considered in connection with the pulse and temperature. When carcinoma is present there is usually no leucocytosis, likewise none in myomata, but after considerable bleeding has taken place in the latter instance, a leucocytosis is evident. In 24 operative cases, Pankow demonstrated a leucocytosis in 22, and this he attributes to the opening of new channels of infection by the operation and the chemotaxic irritation of the cell necrosis in connection with the wound and the absorption of the products of the latter. The leucocytosis regularly diminishes if no wound infection or other complications set in. In labor, during the period of activity of the pains, the leucocytosis can be observed up to the time of the rupture of the membranes. Where the pains are severe and the labor prolonged, a further increase can be noted after the rupture, extending even into the first hour after the placenta is delivered. During the first twelve hours after labor, the number of leucocytes returns to the normal.

Etiology of Prolapsus Uteri.—An interesting theory as to the causation of this condition is advanced by O. Burger (*Archiv f. Gyn.*, Vol. 73, No. 2). He reports a case where in a newborn child there was complete prolapse of the vagina and uterus, degeneration and atrophy of certain groups of muscles in the lower extremities, atrophy of the pelvic floor musculature, as well as sensory paralysis of the lower limbs and the trunk as far as the upper border of the spina bifida. Burger believes that this case will explain the cases of uterine prolapse occurring in women who have never born children (about 3.5 per cent. of the cases). In these instances the factors usually brought forward are insufficient, such as manner of living, occupation, venereal excesses, improper nourishment, inflammations and tumors. Freund attributes the condition to infantilism, others to an insufficient development of the peritoneum. In searching the literature, the author has found 12 cases where this dislocation of the organs was already noted in the newborn child,—ten of these also presented a spina bifida. He therefore sets aside the supposed influence of an infantile condition or the constitution of the peritoneum, and concludes that the association of spina bifida, atrophy of the pelvic floor muscles, and genital prolapse, can be attributed to some disturbances of the sacral nerves which results in the production of the anomalies in question. This view seems to be confirmed by instances seen in older individuals, where some injury affecting the sacral plexus is followed by not only a primary nervous disturbance but also a secondary uterine prolapse.

PEDIATRICS.

Alcohol and Children.—There are manifestly two ways in which alcohol can reach the child, according to G. Carpenter (*Jour. of State Med.*, October, 1904), namely via the parent and by direct access. In the former case the action can be subdivided into (*a*) its action on the sperm or ovum, and (*b*) its action on the maternal organism. Alcohol taken by the stomach may be detected in the ovary or testicle within a very few minutes. The toxic action on the sperm or germ cell may be inferred from the frequency of alcoholic history in the parents of the victims of epilepsy, idiocy imbecility and moral perversion, and to the increased predisposition to the occurrence of organic disease, to various infections (particularly tuberculosis), and to the production of various congenital malformations. One of the causes of the inability on the part of the mother to nurse her child, is ancestral alcoholism. A great part of infantile mortality is to be attributed to the latter phase of degeneration. Alcohol may be traced in the milk within twenty minutes of its ingestion, and for seven or eight hours afterward. Acute or chronic alcoholic poisoning in the infant may be thus caused. The following superstitions and practices are responsible for the administration of alcohol to infants and children. The belief that alcohol will stimulate the child's growth, prevalent in Europe; that gin will prevent colic; that brandy will appease the crying infant. The use of alcoholic confections is not uncommon. Infantile dipsomania is not rare and has been acquired through parental encouragement. The author warns the profession against the indiscriminate prescribing of alcohol for sick or convalescing children without laying emphasis upon the exact amount to be given. The danger of acute alcoholic poisoning by the direct absorption of alcohol from compresses used to reduce fever, must be borne in mind. Even alcoholic fumes have been known to affect young infants. The commonest cause of cirrhosis of the liver in children, is the ingestion of alcohol in repeated doses. There is no evidence to show that Bright's disease or fatty heart is ever produced by this agent in the young. Alcohol expends its main influence in the child upon the nervous system—upon the higher nerve-centers, especially in relation to retardation of development. The outcome of the discussion on the therapeutic value of alcohol seems to be that, although many individual points are still undecided, the weight of evidence tends toward the view that alcohol is a toxic drug, even in small quantities. Any evidence in favor of the employment of alcohol in medicine rests on a clinical foundation. Experiment has demonstrated that immunity in various infections is lowered by the use of alcohol; this has been shown by Abbot, with staphylococci; by Beard, with diphtheria, and by Nicloux, with rabies and tetanus. Many physicians now resort for stimulation to strychnine and caffeine rather than to alcohol. This drug is a greater poison to the child than to the adult.

"Shorten the Time from the Cow to the Baby."—The laws prescribe all manner of requirements for

dairies, cows and the constituents of their milk, but little or nothing is said as to the age of the milk. A. R. Raynolds (*Am. Med.*, October 22, 1904) calls attention to the fact that twelve-hour milk is worth much more from a dietetic standpoint than twenty-four-hour-old milk, while thirty-six-hour milk not only has little food value, but is positively harmful to the young. This applies only to milk in bulk, however,—bottled milk keeping fresh for several days on ice. Milk begins to deteriorate, in digestibility and wholesomeness, from the moment it is exposed to the air. In twenty-four hours after being drawn there will be 400,000 micro-organisms to the teaspoonful, unless checked by cold. The food value is also impaired and the milk rendered poisonous by the growth of these bacteria, so that the young are not only starved but poisoned. Milk intended for the young should be bottled and in the hands of the consumer within twelve hours after milking. The writer claims that no legislation will be enacted making the delivery of twenty-four- to thirty-six-hour-old milk illegal until the public is educated to a knowledge of the evils of stale milk and its murderous effects upon the young.

GENITO-URINARY AND SKIN DISEASES.

Gonorrheal Phlebitis.—A case of this rare complication of gonorrhea is reported by Rosenfeld (*Berl. klin. Woch.*, June 9, 1904), in a young man who developed a marked phlebitis in the lesser saphenous veins about four weeks after an attack of acute gonorrhea had apparently subsided. This gradually disappeared with the use of evaporating lotions. From a study of 26 cases thus far reported, it seems that the affection is usually present in young men during the subacute stage of a first attack of urethritis. In most of these cases an arthritis was also present. Varicose veins were seen in only one instance, so that this condition cannot be looked upon as a predisposing factor. The saphenous vein seems to be most often involved. Pain and edema are the main symptoms and six weeks the usual duration of the affection. The writer believes that the infection is due to the rupture of some hitherto unrecognized focus, probably in the prostate, from which the septic material enters the venous system. The treatment is the same as that of phlebitis in other parts.

Treatment of Urticaria.—The etiology of urticaria is sometimes very simple, sometimes very complex, say F. Tremolières (*Ann. de la Polichnique de Paris*, August, 1904). Acute urticaria may be caused by an irritating parasite, such as a flea or bed bug, or by some irritating plant. Frequently the eating of certain food, such as shellfish, or certain medicines, such as balsams or chloral. Treatment consists naturally of a light purgative, some intestinal antiseptic, such as salol, or benzonaphtol, and quinine or alkalies. Low diet for a few days is necessary. For the pruritus, carbolic or evaporating lotions are necessary. The following prescription is useful:

℞ Carbolic acid, pure..... 2 grams
Glycerin ..... 50 grams
Water. .....150 grams

Lotions of chloral hydrate, 5 to 200, neutral dusting powders of chalk, starch, zinc oxide, with camphor finely pulverized, one to two per cent. A useful ointment is:

℞ Zinc oxide.....3 to 5 grams
Cocaine hydrochlorate (or menthol),
0.3 to 0.60 grams
Vaselin. .....30 grams

Hot or cold baths are not as useful as tepid baths. If the pruritus is rebellious it is necessary to have recourse to a protecting envelope, either an application of a paste or plaster. In the grave urticaria of auto-intoxication prompt treatment by laxatives or emetics, and in case of collapse, subcutaneous injections are necessary. Edema of the glottis is a serious danger of acute urticaria. Hot foot baths and hot applications to the neck, hot fumigations and the administration of ether, Hoffman's anodyne and acetate of ammonia. In spite of this, sometimes tracheotomy is necessary. In chronic urticaria, careful dieting, forbidding the use of wine and other alcoholic beverages, acid or fermentable, or indigestible foods of any kind. Bowels should be moved by gentle laxatives. The dyspepsia, or atomic condition of the stomach is best treated with the use of absorbing powders, antiseptic or alkaline, such as charcoal, chalk, sodium bicarbonate or magnesia. Renal insufficiency may exist or the uric acid diathesis. A definite vasomotor neurosis may be present. All of these call for definite treatment. The use of mineral waters properly selected is valuable.

Eye-strain as a Causative Factor in Sinusitis.—That eye-strain holds an important place in the production and maintenance of this conditon, is the statement made by W. L. Phillips (*Am. Med.*, September 17, 1904), although he does not claim that all forms of accessory sinusitis are due to it. The fact first to be ascertained in making a diagnosis of frontal sinusitis is at what early age do the frontal sinuses develop, for they are not present at birth. Observations vary on this point, but it may be accepted that the sinuses are present at the sixth year of life. Nationality must also be regarded, and investigation has shown that in the Germans the frontal sinus attained the greatest development, with the other nations following, the negro and the Chinese being at the end of the list. Patients who suffer from frontal sinusitis complain of frontal headaches, pressure above the eyes, inability to concentrate thought, dizziness, nausea, injected conjunctiva, defective vision, etc. The only positive way of making a diagnosis is to establish the presence of pus within the cavity. Care must be taken to exclude supra-orbital neuralgia, and where there is doubt between sinusitis and meningocele or aneurism of the ophthalmic artery, it is well to draw off some of the fluid for microscopical examination. In this connection it must be remembered that this particular form of sinusitis is limited to an inflammation of the lining membrane which varies from a slight congestion to a purulent condition. The nervous system bears an important part in the production of secretion. To produce clear vision with an astigmatic eye, all the residual nerve energy must be used up, because of the increased work required to focus an eye that has different meridianal lengths. This drain of nerve force robs other parts of the required energy to keep up a normal condition, and acts as would a division of the vasomotor nerves dilating the blood vessels and increasing the amount of mucus in the frontal sinus. If this secretion is allowed to accumulate from day to day, it will eventually become infected by germs entering the sinus from the nasal cavity. The writer is unable to state what percentage of sinusitis is due to eye-strain and what percentage may be cured by glasses, but in the cases in which he tried this method, he was usually successful. A series of ten cases is detailed, in which no special treatment was directed to the sinusitis, other than proper glasses. It is advised, however, that local treatment be also instituted in addition to the other.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, NOVEMBER 26, 1904.

PROGRESS IN PROSTATIC SURGERY.

The nature of the advance in the radical treatment of enlarged obstructing prostates is so important and withal so life and misery-saving that new and trustworthy methods cannot too rapidly be spread abroad.

The secret of the advance is to be found in the more thorough knowledge of the pathology of the organ. This has come, in the case of the prostate, with peculiar slowness. Although a correct view of the cause and nature of the morbid process was entertained and published by Sir Herbert Thompson over forty years ago, few surgeons took the trouble to verify his observations or to foster his teachings, with the result that, if we are to believe the views of some recent workers, a false presentation of the subject has, until very recently, been universally taught.

Few indeed are the practitioners who do not from early teaching conceive of the organ as having two lateral lobes, and, when obstructing, an offending central lobe. Even that almost inhumanly accurate tome, Gray's Anatomy, makes the statement that the prostatic portion of the urethra "passes through the gland." It does no such thing. True enough, this is what appears on first inspection to be the actual condition, but, as Thompson demonstrated, and as has recently been most conclusively proved, the two lateral lobes, each covered with an inner and an outer capsule, simply reach around and envelop the canal. How different is this from the boring-out process described by Gray.

Further, as to the so-called "middle lobe." It does not exist. It is quite true that in certain isolated and very rare instances there may be adenomatous tumors springing from the lateral lobes which, when single and favorably placed, may assume the proportion of a "lobe." The majority of "middle lobes," however, are simply the more or less symmetrically overdeveloped lateral expansions of the *two prostatic glands.*

If we are to believe the testimony of an acknowledged authority on these matters, it will, in the future, be necessary to entirely change our prostatic nomenclature. J. P. Freyer, in a recent exhaustive article (*Lancet* 1, 1904, p. 870), speaks as follows of the gross pathology of the hypertrophied organ: "The prostate is, in reality, composed of twin organs of apparently purely sexual function, which, in some of the lower animals, remain distinct and separate through life. So they exist in the human male during the first four months of fetal existence. After that period, in the human fetus, they approach each other and their inner aspects become agglutinated except along the course of the urethra, which they envelop in their embrace. These two glandular organs which constitute the lateral lobes of the prostate, though welded together to constitute, as it were, one mass, remain practically as distinct as the testes."

If, therefore, based on its gross morphological appearance, the gland or glands is to be spoken of as a single organ, this must be only with the distinct understanding that developmentally, and pathologically as well, the prostate is, in reality as double as the testes.

Suppose success to have at length crowned the efforts of those who are striving to undermine fallacious old prostatic teachings and to blot out hereditary genito-urinary superstitions, what result may be looked for?

We hope that that dread blight of old age, "catheter life," may cease to exist. Be it said that had Thompson's warnings, sounded over forty years ago, been heeded, many a man in the prime of intellectual and physical vigor would not have been dragged into an untimely grave

by this ghastly and forbidding specter. Surgery is to blame for this lapse in the care of old men. Had fewer ovaries been sacrificed and more prostates dug out, may not both men and women have been happier and longer lived?

If, as has been repeatedly stated, catheter life, or catheter death, as it should more aptly be called, can at the very outside average no longer than four years; if, as is held on the very highest authority, death is the penalty for using the catheter in one hundred per cent. of cases, is it not time for us all to wake from our lethargy and urge the perfection of the ideal operation for the diseased prostate?

THE UNVEILING OF PRENTICE.

While it may be true, as the French very epigrammatically state, that it is "the first step that tells," yet it is unquestionably the last one that gives a finished value to the whole and adds an increased worth to the collection, which, if incomplete, would be of but little profit to any one. *Finis coronat opus* and young Lochinvar would cut but a sorry figure in his immaculate evening clothes were he left destitute of the conventional white tie, while the most valuable of paintings would show to poor advantage without the accustomed frame. A freshly papered wall is lost without its border, and though it is the first brush which takes the mud from off our shoes, yet it is the last and final polish that renders them of use to us.

And this is as true of medicine and medical remedies as it is of an issue of postage stamps or a collection of coins. For while they may each and individually be possessed of a certain value, the total aggregate is largely increased from the fact that they represent a complete and finished series. Thus the owner of the celebrated proprietary remedy in the West who advertised that his medicine "cured chills and all other diseases, and was good to eat on bread," completed his cycle, as the specifics otherwise in use were not adapted for luncheon relishes, while the customary *hors d'oeuvres* of the bills of fare are not possessed of therapeutic virtues. The specimens of a single plate of Hogarth's "Rake's Progress" or Bartolozzi's "Four Seasons" are of infinitely less relative value than the completed sets, and this is a fact that should be as apparent to the physician as it is well known to the connoisseur.

The practice of medicine has been, and, it is to be feared, always will be, a thing of fads and fashions, not only in the treatment but in the etiology of disease, and practitioners of even a dozen years' experience can look back and remember how indiscriminately all the ills that flesh is heir to have been attributed to the same cause, and how each and every organ of the human body has been held under suspicion for producing trouble by reflex action without a clear verdict having been rendered against any one of them. Thus we had the epoch of "malaria," when every head or backache, every feeling of general malaise was at once attributed to it, and the patients without further examination were immediately saturated with quinine. This, with time and its healing influence as an adjunct generally sufficed, and the snap diagnosis was confirmed. The late Dr. Oliver Wendell Holmes was in the habit of saying that "Malaria was a large box and that there was a great deal in it," but we doubt if it ever could have held a thousandth part of what it was charged with, for malaria, as a rule, like Dr. Wiley's Scotch Whisky, is only produced in a pure state, in a quantity sufficient for home consumption. Its symptoms and effects are pathognomonic of the disease and are highly characteristic of it. It cannot, however, be claimed as a universal factor in the rundown condition that is liable to attack every one in the spring and fall.

This epoch of malaria was followed by the era of "Nervous Prostration," and every anemic American woman who had tried in vain to combine the pleasures of society with the duties of maternity was placed forthwith on her back in a "rest cure," and the overworked nervous man of business was patted on the shoulder with the pleasing assurance that there was "nothing organic," while the unprofessional ears of both were soothed with the generic shibboleth of *Neurasthenia*. Then came, from our national tendency toward specialism, a further splitting up of all the fruits of overtaxation and new remedies for their cure. We had "brain fag," "eye-strain" and the adaptation of spectacles for the relief of almost every pathological condition that had ever existed. Glasses for the neutralization of ills that had been inherited from the sins of our fathers, and which, without them, would be visited upon our children even unto the third or fourth generation. In fact, up to the present time, inebriety is practically the only serious condition that some enthusiast or other has omitted to ascribe to an ophthalmic origin.

Now, however, the collection is complete, and the missing link has been supplied. For the gap has been filled by one Dr. Chalmers Prentice, who is described in the report as "a prominent Chicago oculist," who has declared solemnly to the National Optician's Convention in Milwaukee, that "alcoholism can be cured by properly fitted eyeglasses." "He found," he states, "that inebriates generally suffer from certain deviations in the accommodation and convergence of the eyes, and he had noticed in many cases that glasses which remedied these derangements of sight had also the effect of diminishing the patient's appetite for liquor." Dr. Prentice also described a dipsomaniac being fitted with glasses and then losing all desire for drink after thirty days.

What other things Dr. Prentice has "noticed" he does not say, and it is greatly to be regretted that he has painted his picture with the broad brush of the impressionist rather than with the detail giving one of the miniaturist. For instance, he might have told us *what* the certain deviations of the convergence were that pointed so strongly toward the red light of inebriety, and explained why it was that when a person addicted to strong drink arrived at the age to lose his accommodation he did not lose his craving for liquor, too. He might also have given some further information concerning his quoted note, which was redeemed in thirty days after date, both in regard to his age and the amount of liquor that he had been in the habit of consuming.

Now drunkenness is a terrible evil, either in an individual or a community. It is a curse that has not only been the direct means of shattering many homes, and scattering peaceful firesides, but it is collaterally responsible for the formation of the W. C. T. U. (with the abandonment of the Army Canteen), the production of such lurid plays as "Ten Nights in a Bar-room" and the infliction on a sober and long-suffering public of the song of "Father, dear Father, come home with me now," so that any means available serving for its alleviation should meet with the fullest investigation. It may be in this particular case that headache had driven the sufferer to drink and that this being relieved by glasses, he returned to his normal condition, or possibly he was not a victim to a complete attack of mania a potu. He may have been simply "threatened" with it, as was the man at Oshkosh who lately testified on the stand, in regard to his responsibility, that he *almost* had delirium tremens, as evidenced by his seeing a blue owl on each of his bed posts.

But be this as it may, we cannot predicate a theory on a single case. One patient does not constitute a practice, nor does one swallow make a drunkard. So we must wait for further information from Dr. Prentice. Meanwhile, we cannot imagine that he will meet with much success in his educational efforts among the opticians. Missionaries have, ere this, been killed and eaten by their converts, and it is not always the engineer alone that has been hoisted by his own petard. The Pennsylvania legislature has declined to grant franchises to the Get-wise-quick Optical Institutes, and we confess that this delivery of lectures to them smacks overmuch of a recent advertisement in a woman's journal, "The whole science and practice of bridge whist in two, short, easy lessons."

Art is long, time is fleeting and, as these "expert refractionists" will discover sooner or later—

> Asthenopia is hypermetropia,
> Myopia is as bad—
> Insufficiency doth bother me,
> And refraction drives me mad.

ECHOES AND NEWS.

NEW YORK.

Subway Air.—According to analyses made by Dr. C. F. Chandler, the subway air of the city, so far as its oxygen content is concerned, is practically the same as the air of the street. What is wanted by the citizens, however, is not the sensational clap-trap of those who thought they found the air deficient in oxygen, nor the hasty contradiction by officially appointed representatives, but a careful, complete, and trustworthy study of the entire problem. We do not want 16 analyses, nor 36, but many hundreds taken at various times and sundry places.

Dr. Dew Wins Suit.—Henry E. Howland, as referee, has handed down his decision in an interesting suit brought by Dr. J. Harvie Dew, of New York, against the estate of Oliver W. Buckingham. The referee grants to Dr. Dew $10,000 for continuous medical services for five years and $10,000 for furnishing a home for the patient for three years.

Our City Parks.—Corlears Hook Park is located on New York's East Side just where the river makes a magnificent bend opposite the Brooklyn Navy Yard. With the exception of the Battery, it is by far the best site for a river front park on Manhattan, writes *Charities*. But a narrow strip of land between the park and the water is owned by private parties. And the exact angle of the bend has been held, so it has always been declared, by an estate which could not dispose of it to the city because the heirs were minors. During the Low administration, East Side social workers centered their efforts on the acquisition of the river front strip. The project was practically through the Board of Esti-

mate and Apportionment in December, when a technical flaw was discovered in the official advertisement, and the matter was laid over with assurances from the hold-over members of the board that the incoming administration would take it up. No steps have been taken. Meanwhile ground is being broken for a ten-story mill on the point-site which the officials had stated could not be purchased, and report has it that the water front may similarly be built upon, shutting in the park. There is only one possibility of forestalling the erection of the mill at the point. That would be an exchange of water front property a few blocks north now used as a city yard. It is a bad chance, but a chance. But there is no reason why any attempt to buy up and build up the river shore before the park cannot be forestalled by the city authorities. The incident shows, once more, the need for coordinated, intelligent action affecting the park situation in New York. Not only are the wrong sites likely to be purchased, but the right sites are being lost.

Politics and the Pneumonia Commission.—Even the *Pneumococcus*, deadly enough already, has worked its wires and gotten its "political pull" in fine working order. This time politics acts as an obstructionist. "The Civil Service Commission has ruled that the commission of medical experts appointed last year by the city authorities to investigate cases of acute respiratory diseases in the city with a view to lessening them, cannot employ assistants in other cities unless the physicians so employed first come to New York and undergo a municipal civil service examination."

Thus if the "Pneumonia Commission" desire to employ specialists in particular branches of the investigation of this most dread disease, be they Englishmen, Frenchmen, Eastern or Western, and New York should have the best; they must needs come to New York and pass an asinine civil service examination. The idiocy of this ruling is beyond comprehension.

State of New York—State Civil Service Commission.—Open competitive examinations will be held in various cities throughout the State, December 3, 1904, for the following positions: *Resident Physician*, State Industrial School, Rochester, $1,500 and maintenance. Candidates must be licensed medical practitioners of New York State and have had at least one year's experience on the staff of a public general hospital. Subjects of examination and relative weights: Materia medica and therapeutics, theory and practice, surgery, hygiene and sanitation, pathology and diagnosis, hospital management, 7; experience, education and special training, 3. *Fourth Grade Physician.* This examination is intended to provide eligibles for the position of Medical Interne and other medical positions of similar grade in the State hospitals and other State and county institutions. The usual salary is $600, with maintenance, including quarters, board, laundry, etc. It is open to men or women who have graduated within three years from a registered medical school. Candidates of the Homeopathic school will be admitted without regard to date of graduation. Candidates may be either non-residents or residents of New York State *and a license to practice is not required.* Subjects of examination and relative weights: Written examinations covering anatomy, physiology, chemistry, materia medica, therapeutics obstetrics, surgery, theory and practice, 8; education, experience and personal qualifications, 2. In order to be eligible for appointment, candidates must obtain a minimum standing of 60 per cent. on the written examination and 60 per cent. on education, etc., and a general average of 75 per cent. The medical service of the State comprises the 16 State hospitals, with about 160 salaried medical positions and about 30 positions in the Pathological Institute, the Craig Colony for Epileptics and other institutions. All higher medical positions, from assistant physicians at $1,200 to $1,500 and maintenance, to superintendents at $3,500 to $4,500 and maintenance, are filled by promotion through regular grades from that of sixth grade or junior physician. The State service presents one of the very best opportunities not only for training in psychiatry, but for general and special medical, surgical, laboratory and post-mortem work as well. Persons desiring to enter these examinations must execute applications on forms supplied by the Commission and file them in the office of the Commission before noon of November 28. Application blanks and further information regarding the character of the service and the nature of the examination for Fourth Grade Physician may be obtained by personal or written application to the Chief Examiner, State Civil Service Commission, Albany, N. Y.

In Memory of Dr. William Rice Pryor.—The faculty of the New York Polyclinic Medical School and Hospital, through its committee, appointed at the annual meeting, held November 10, 1904, *Hereby Resolves*, That the death of Dr. William Rice Pryor, Professor of Gynecology in the New York Polyclinic Medical School and Hospital, which occurred on August 25, 1904, was a great loss and sorrow to the Faculty of the Polyclinic and to his many friends. Graduated from Princeton College in 1878, from the College of Physicians and Surgeons in New York in 1881, and from Bellevue Hospital in 1882, Dr. Pryor was particularly well equipped for his life work and the eminent position he attained in the special branch of medicine to which he gave his attention was due in no small degree to this thorough preparation. His ability, perseverance, originality and thoroughness were recognized by all who knew him, and will always serve as a stimulus to his fellow workers. Throughout his entire career he was in the highest sense the friend of the needy and the afflicted. The amount of time he devoted to charity work was enormous, and in many instances, where those under treatment could not afford to pay for little delicacies needed, he supplied them from his own purse, besides giving his services free. His attention to details and his personal supervision and care of those he treated was most painstaking.

His services to the Polyclinic were most valuable. Appointed as Clinical Assistant to the Chair of Gynecology in 1886, he filled all the intermediate positions most creditably until in 1895 he was made full Professor of Gynecology. His clinics drew students from all over the country, and his writings attracted marked attention both at home and abroad. He was a frequent contributor to medical literature, and shortly before his death had completed a Text-Book of Gynecology. We assure his bereaved family of our deepest sympathy, and do hereby resolve that this record be inscribed at length upon the minutes of the Faculty, that it be published in the medical journals, and a copy, suitably engrossed, be sent to the family of our late colleague. W. R. Townsend, *Chairman;* J. Riddle Goffe, Brooks H. Wells, *Committee.*

PHILADELPHIA.

The Jefferson Medical College Library.—The report of the librarian of the Jefferson Medical College Library for the year just ended showed some interesting and noteworthy facts concerning the contents and circulation of the college library. There were 3,009 volumes in the library, of which

439 were added during the year; 203 by gift, and 236 by purchase and binding, the largest gift being 78 volumes from the library of the late Dr. C. W. Horner. There are fewer than two thousand volumes of general text books in the library, and from these there was a circulation of 10,663 volumes.

Large Award for Personal Injury.—One of the largest awards ever made in the Philadelphia courts for personal injuries was lately made in the case of Mrs. Cecilia McGrew. In 1902 a street car in which the patient was riding collided with a wagon and threw her to the floor. She has since been unable to walk. In her suit against the Philadelphia Rapid Transit Company she was awarded $17,501 damages.

Vaccination Law Defective.—Decision in the case of a physician accused by the Bureau of Health of issuing a false vaccination certificate has freed some hundreds of the same charge. The certificate was based on a vaccination of a child three years ago, the mother stating it had been successful; it appears not to have been. The magistrate censured the physician for carelessness in giving the certificate, but could not hold him for violation of the law, as no time limit is specified. The decision will probably result in an amendment to the act of Assembly relating to vaccination.

Chorio-Epithelioma.—An instructive case of this new growth was reported at the Philadelphia Pathological Society November 10, by Drs. D. L. Edsall and W. E. Robertson. The patient was a woman of twenty-five years, who complained only of gastric symptoms. She had been married four years, and had had no children or abortions. Fifteen weeks before admission she had a hemorrhage from the uterus. Repeated physical examinations revealed nothing abnormal. Autopsy showed the presence in both lungs of nodules varying from a pea to a hazelnut in size. Similar growths were found in the liver, intestines and the uterus. The latter were encapsulated and apparently had no relation to placental tissue.

CHICAGO.

Dr. Geo. F. Butler.—In announcing his retirement as medical superintendent of the Alma Springs Sanitarium, Alma, Mich., and return to his former home, Chicago. Dr. Butler desires to convey his assurance of personal interest in his former clients. His return to Chicago does not mean withdrawal from the practice of medicine. On the contrary, Dr. Butler will limit his business to medical work exclusively, and has arranged excellent facilities for the care and proper treatment of nervous and chronic invalids in the city and from out of town.

Appointment of Dr. Carlson.—Dr. Anton Julius Carlson has been appointed associate in physiology at the University of Chicago.

Unprofessional Conduct.—This was the label placed upon the division of fees, which is said to obtain among certain physicians in Chicago and Illinois towns by the passage of the following resolution offered at a recent meeting of the Council of the Chicago Medical Society: "Any member who is guilty of giving or receiving a commission or of entering into any arrangement for the division of a fee for professional services, which arrangement is not known and fully understood by the patient or party by whom such fee is paid, shall be guilty of unprofessional conduct." A similar resolution was introduced at a meeting of the Chicago Gynecological Society, held November 18, which contained a rider requiring all new members to assent to the change by signing the Constitution, but leaving it optional whether the older members shall do so or not. The resolution was warmly discussed, but will again come up before a subsequent meeting before its adoption or rejection.

Injunction Against Civil Service Examination in Cook County Hospital.—Physicians of the three schools of medicine, to the number of 350, petitioned Judge Dunne for an injunction restraining the county authorities from placing members of their profession at the Cook County Hospital under civil service, a project for which examinations were scheduled. The concerted action is the result of a combination of three separate movements against the plan. Representatives of the several medical colleges and of the three different schools of medicine met in conference and after canvassing the situation agreed to bring a joint suit. The result has been that the matter will be taken into court. The grounds on which the restraining writ was asked are the services of physicians to the hospital are gratuitous, and therefore do not come within the jurisdiction of the merit law which covers paid employees. A test would be unfair to men of national reputation who are on the attending staff, inasmuch as technical knowledge will receive high markings. Students fresh from their books are said to be better qualified to answer certain questions than physicians of long experience, whose knowledge has become practical rather than theoretical. The project would serve to perpetuate a constant staff and new men would find difficulty in getting into the service. The appointment of the examining board was unfair, as thirty-two of the forty-two examiners are Rush Medical College men. The County authorities have been enjoined from placing members of the medical profession under civil service rule. The court exprssed the opinion that the County Board had exceeded its authority in attempting to hold an examination for positions. A final order will be entered on the bill for injunction by Judge Tuley in a few days.

State Conference of Charities Suggests Improvements in Institutions.—At a meeting of the State Conference of Charities, held in Rockford, Ill., November 16, Dr. V. H. Podstata, of the Dunning institutions, made the report of the Committee on the Care of Epileptics, in which the establishment of a colony by the State is urged as of extreme necessity. Reports gathered by the State Board of Charities indicate that there are about three thousand epileptics in Illinois. He displayed plans for cottages designed by the State architect, showing that the two-story cottages could be erected at a cost of about $300 per inmate. He recommended single-story cottages in preference to the double story plan. As a beginning for the colony, it is proposed to ask the Legislature for an appropriation of an amount at least sufficient to purchase one thousand acres of land for the site. Most of the provisions asked for by the Conference look toward legislative action. A series of resolutions adopted recommend the custody of all feeble-minded women by the State; the transfer of all insane patients from the various County poor houses to the State institutions; the transfer of the Dunning Asylum of Cook County from the care of the county to the State; the establishment of an epileptic colony and an appropriation for that purpose from the State legislature; the passage of a bill compelling the disinfection of houses in which there has been death from consumption; more adequate appropriation for the State factory inspector's office, to enable a more rigid enforcement of the laws pertaining to space and light.

CANADA.

Inebriate Reform Society of Ontario.—Last week this society was organized in Toronto, the object of the new organization as set forth in the draft constitution submitted being to promote the adoption of the probation system for the reformation of inebriates; to promote the adoption of the "home" or dispensary treatment in suitable cases; to promote the establishment of municipal sanitoria for indigent inebriates; to seek the necessary permissive legislation as provided in the proposed bill now before the Ontario Legislature; to distribute inebriate reform literature, and to favor long sentences for confirmed habitual drunkards. The fee for the membership is placed at $2; life membership, $25; and funds will be obtained from Government grants, city and county grants, and from private sources. Now that this movement in Ontario is to be pushed along by a well-organized society, it will be expected that the Government will act, and act promptly in the matter. Among those who are mentioned as Hon. Vice-Presidents are Professor William Osler; Dr. W. B. Geikie, Dr. James Thorburn and Dr. R. W. Bruce Smith, of Toronto; Dr. A. M. Roseburgh, who has been identified for a number of years with this matter, has been made permanent secretary of the new organization.

Central Hospitals for Consumptives in Ontario.—A few years ago the legislature of the Province of Ontario passed an act providing that when counties or municipalities or groups of counties or municipalities desired to erect and maintain hospitals for their consumptive poor that the Government would furnish aid toward the erection and maintenance of these. What promises to be the initial step in this direction was taken last week when representatives of five leading counties in Ontario met in conference at Galt and agreed that it would be in the interests of their consumptives if a sanatorium were erected for the five counties of Brant, Oxford, Waterloo, Wellington and Perth, and will immediately lay the matter before the respective county councils of these municipalities. Dr. Radford, of Waterloo County, presided at this conference, and gave the statistics of consumption and its ravages in the Dominion. According to his lights there are about 40,000 consumptives in the Dominion, and about 15,000 in the Province of Ontario. The deaths average about 6,000 throughout the Dominion annually; in Ontario last year they numbered 2,694; in his own county of Waterloo they numbered 17. This movement is an important one, as no doubt other groups of counties will follow suit upon the action of the above named.

British Columbia Medical Examinations.—The examinations of the College of Physicians and Surgeons of Britsh Columbia were held lately in Victoria, the seat of government of the province. Thirteen candidates presented themselves, of whom nine received first-class honors, permitting them to practice their profession in British Columbia. One of these was a lady, Dr. Eliza Anderson, of New Westminster, who will practice her profession in that town. The Examining Board for the present year consists of the following: Dr. W. J. McGuigan, Mayor of Vancouver; Dr. J. C. Fagan, of Victoria, secretary of the provincial board of health of British Columbia; Dr. R. Eden Walker, of New Westminster; Dr. A. P. Proctor, of Kamloops, President of the British Columbia Medical Council; Dr. J. M. Lefevre, of Vancouver, who is at present on his way to England; Drs. O. M. Jones and J. C. Davis, of Victoria.

GENERAL.

National Association for the Study and Prevention of Tuberculosis.—At a meeting of the Board of The National Association for the Study and Prevention of Tuberculosis, held in New York, November 16, 1904, it was decided to hold the first annual meeting of the Association in Washington, D. C., on the third Tuesday of May, 1905; that arrangements be made for a two days' meeting, in which there should be one or two general sessions with distinguished speakers upon the broad topics of tuberculosis, and special meetings of the three following sections: (1) Sociological, (2) Pathological and Bacteriological, (3) Clinical and Climatological; and, that so far as possible, these sectional meetings should not conflict one with another, each section to be presided over by gentlemen distinguished in their respective work, and only papers of undoubted merit and interest be presented. The membership of the Association includes a large proportion of the most eminent workers in the subject of tuberculosis throughout the country, and it hopes to make its first annual meeting an important one in the crusade in this country against tuberculosis.

Epileptic Colony Fakirs.—A recent Chicago story of imposture in the name of charity, affords a text for charity givers and students of sociology. This is ably set forth by E. P. Bicknell, in a recent number of *Charities*. The lessons which may be drawn from this story are rather obvious, but it may be allowable to refer to two or three of them:

1. The pathetic demand for a cure for epilepsy and the totally inadequate response of medical science, drives victims of the disease to grasp at the promises of quacks and irresponsible promoters of so-called "homes" and "sanatoriums."

2. The universal respect for the garb of the nurse and of the sister of charity, makes those garbs a peculiarly effective aid for the collector who asks money in the name of charity.

3. The ease with which the common, unthinking impulse of charity may be exploited almost with impunity, offers a constant temptation to the unscrupulous.

Five or six years ago William Held established what he called the Illinois Home for Epileptics, in Chicago. It was a private institution and his advertised purpose was to treat epilepsy by methods which it was promised would cure the disease. Mr. Held at that time was not a physician, and his methods of treatment included little or no medicine. The home had two departments—pay and charity. To support the charity department, Mr. Held employed as a solicitor a woman named Rachel Gorman. Rachel Gorman was not and is not a graduated nurse, but she arrayed herself in a striking costume which suggested at once to all beholders that she belonged to some order or group of nurses. She collected money from the down-town business district, but frequented the saloons and race tracks, where it was said she received generous contributions. After two or three years Mr. Held discharged Rachel Gorman. The reasons he gives for the discharge are that the woman drank to excess; that her character is not such as is consistent with the work which she was employed to do, and finally that she did not make a satisfactory accounting of her collections.

The Illinois Home for Epileptics, after moving from place to place in Chicago, was transferred finally to Arlington Heights, a suburb, where about two years

ago the building was destroyed by fire. The home has not been re-established.

After leaving the employ of Mr. Held, who since the opening of his home had obtained a degree of doctor of medicine, Rachel Gorman persuaded S. F. Cleveland, and another man, known as "Doctor" Gibson, to join in the establishment of an enterprise which was given the title of the American Chronic and Epileptic Association. Headquarters were established at number 1015 North Clark Street. Mr. Cleveland was manager, Rachel Gorman occupied the "charity chair," and "Doctor" Gibson attended to the medical treatment. Affairs did not go well with the American Chronic and Epileptic Association. Rachel Gorman charged Mr. Cleveland with various shortcomings. Mr. Cleveland declared that Rachel Gorman did not "turn in" as much of her charity collections as agreeemnt called for, and that she was intemperate and associated with bad characters. The woman employed several assistant collectors, and garbed them all. Patients were not cared for at the home, but came there once a week for treatment. It was apparent that the number of such patients was exceedingly small. "Doctor" Gibson was said to administer a certain kind of drug or medicine alike to all comers. What this medicine was, did not appear. Mr. Cleveland complained bitterly that he had been deceived in "Doctor" Gibson, asserting that when he entered into the partnership he had understood that Gibson was a doctor of medicine. An open rupture among the officers of the home led to Rachel Gorman and "Doctor" Gibson leaving Mr. Cleveland and starting an organization of their own, known as the American Epileptic Charity Association, but later as the "Rachel Gorman Home for Epileptics." The Rachel Gorman Home was said to be located at Round Lake, Ill. Mr. Cleveland moved to 1065 North Clark Street where he opened a home for epileptics and called it the Cleveland "Neurotarium." Mr. Cleveland employed one Dr. W. S. Maharg, as physician to his institution. Dr. Maharg claimed to have an unfailing remedy for epilepsy; also for tuberculosis.

Rachel Gorman, with a corps of assistant solicitors in uniform, began an extensive campaign for funds. Cleveland's Neurotarium also put a corps of solicitors in the field garbed as nurses, the costume being different from that of the Gorman collectors. During a period of perhaps eighteen months Rachel Gorman sent seven patients to board in the farmhouse of a Mrs. White, of Round Lake, Ill. In June, 1904, Rachel Gorman purchased a house in Blue Island, and from that time the Rachel Gorman Home for Epileptics was advertised to be there. A city office of the home was maintained at 91 Wisconsin Street. The number of solicitors, in striking green garb, increased to eight or perhaps more. Certain of these women were unfavorably known to the police. Some of them, on being interviewed, stated that the average daily collections for each solicitor were about $6. It continued to be quite impossible to get any evidence that a larger amount of charity was being performed than was expressed by the care of one or two epileptics at the house in Blue Island. Dr. Maharg, physician to the Cleveland "Neurotarium," not satisfied with the income of that institution, opened a dispensary for the treatment of consumption at 954 North Clark Street. This enterprise he called The Nazarene Medical Mission. He employed a number of solicitors, put them in a garb suggesting the trained nurse, and set them to raising money. The neighbors noticed that these women would enter a house of the number given in the morning, would presently reappear in nurses' garb, and that in the evening they would return to the house, leaving the uniform and depart in street dress. The matter was brought to the attention of the police who raided the house in October and found it vacant, except for the belongings of the solicitors. Dr. Maharg was arrested and in the police court fined $100 and costs. Not being able to pay the fine he was sent to the House of Correction. This was the beginning of police activity so far as epileptic charities were concerned. Rachel Gorman's office on Wisconsin Street was next raided, and the uniforms of her collectors seized, together with papers and printed matter. Records showing their operations were captured in this way. These showed that Rachel Gorman and her corps of assistants were collecting a surprisingly large amount of money from the charitable people of Chicago. One slip, dated July 8, 1904, showed collections made amounting to $164. Governor Richard Yates and William Jennings Bryan were shown to have each given $100. The statement was made that Rachel Gorman had paid $3,000 upon the Blue Island property which she had purchased, and that she had a bank account of several hundred dollars on the date of the raid. She had sent her uniformed collectors to the State Republican and Democratic conventions at Springfield, and had other collectors operating in St. Louis. A deposit slip was discovered showing a bank account opened in a St. Louis bank with $358 as a beginning. A warrant was issued for Rachel Gorman's arrest, but she was found confined to her home in Blue Island as the result of an injury received, as she explained through falling on a defective sidewalk. She threatens to bring a suit for large damages against the city of Blue Island because of this injury. The Blue Island City Council has passed an ordinance prohibiting a home for epileptics within the city limits, and Rachel Gorman has been notified to move out. At present her threat to sue the city for damages seems to restrain the Blue Island authorities from proceeding actively against her. The police have warned the proprietor of Cleveland's "Neurotarium" that his collectors must be kept off the streets, under threats of arrest and the closing up of his institution. Other "charity" schemes have been recently checked, also, and evidence relating to the true character of two or three more has been submitted to the police authorities and is now under consideration.

International Surgical Society.—The first Congress of the International Society of Surgery will take place in Brussels, in September, 1905, under the presidency of Professor Th. Kocher, of Berne. The order of discussion will comprise: "Value of the Examination of the Blood in Surgery," to be discussed by Dr. W. W. Keen, of Philadelphia; Dr. Sonnenberg, of Berlin; Dr. Ortiz de la Torre, of Madrid, and Dr. Depage, of Brussels. "Treatment of Prostatic Hypertrophy," by Dr. Reginald Harrison, of London; Dr. Rovsing, of Copenhagen, and Dr. von Rydygier, of Lemberg. "Surgical Intervention in Non-cancerous Affections of the Stomach," by Dr. Mayo Robson, of London; Dr. von Eiselsberg, of Vienna; Dr. Mattoli, of Ascoli Piceno; Dr. Monprofit, of Angiers; Dr. Rotgans, of Amsterdam, and Dr. Jonnesco, of Bucharest. "Treatment of Joint-Tuberculosis," by Dr. Bier, of Bonn; Dr. Broca, of Paris, Dr. Bradford, of Boston; Dr. Codivilla, of Bologne, and Dr. Willems, of Gand. "Treatment of Peritonitis." This subject will be discussed by Dr. M. Lennander, of Upsala; Dr. Friedrich, of Leipzig; Dr. Lejars, of Paris, Dr. A. McCosh, of New York; Dr. Krogius, of Helsingfors, and Dr. de Isla, of Madrid. "Surgical Diagnosis of Diseases of the Kidney," will be discussed by Dr. M. Albarran, of

Paris; Dr. Kümmel, of Hamburg; Dr. Giordans, of Venice, and Dr. Lambotte, of Brussels. All communications should be addressed to Dr. Ch. Willems, 6 Place St. Michel, Gand, Brussels.

The Japanese Red Cross Society.—The London papers are printing an interview with Miss McCaul, who was received a few days ago by the Queen on her return from an important mission to the Far East, having for its object the study of the Japanese Red Cross Society. A detailed report of the Japanese military nursing system is now in the hands of her Majesty, and an account of the mission will shortly be published in book form.

There can be no doubt that the Japanese are ahead of Great Britain in the matter of surgical and medical outfit, and most certainly in the management of field hospitals. This is due to the tremendous forethought and wonderful inventiveness of the Japanese. Yet rigid economy is observed. There are many useful lessons to be learned from the Japanese. The equipment of the hospitals is magnificent, and the fact that their system goes like clockwork is due to the intense esprit de corps among all their medical men. Miss McCaul was thoroughly delighted with what she saw of the care of the wounded. The medical science and nursing skill of the Japanese are wonderful. No woman nurses are allowed at the front, all the work being done by men. During war the female nurses are drafted into the big reserve and stationary hospitals in Japan, where they replace the male nurses, who are dispatched to the front. They are all Red Cross nurses, and are kept as a reserve. After a course of training they sign for sixteen years' service, but are free to follow their ordinary avocations so long as they report at intervals, so as to be available when wanted.

Southern Surgical and Gynecological Association.—The seventeenth annual meeting will be held at the Hotel Hillman, Birmingham, Ala., December 13, 14 and 15, 1904. The following porgram has been arranged: Presidential Address, by Dr. Floyd W. McRae, of Atlanta, Ga.; Address of Presentation of Davis Monument, by Dr. C. M. Rosser, of Dallas, Texas; Address of Acceptance on Behalf of State of Alabama, by Gov. R. M. Cunnigham, M.D.; Address of Acceptance on Behalf of the City of Birmingham, by Hon. W. M. Drennan. Titles of Papers: Gall Stones in the Ampulla Vater, by Dr. A. H. Ferguson, of Chicago; A Method of Uniting Intestines of Very Small or Unequal Caliber, by Dr. J. Shelton Horsley, of Richmond, Va.; Enterostomy, by Dr. J. W. Long, of Greensboro, N. C.; The Treatment of Fecal Fistula, by Dr. Stuart McGuire, of Richmond, Va.; Intestinal Obstruction, by Dr. D. F. Talley, of Birmingham, Ala.; The Abuse of Purgatives Before and After Abdominal Section, by Dr. I. S. Stone, of Washington, D. C.; Observations upon the Aseptic Technic of Abdominal and Pelvic Surgery, by Dr. Henry T. Byford, of Chicago, Ill.; The Employment of Celluloid Plates for Covering Defects in the Skull, by Dr. W. Perrin Nicholson, of Atlanta, Ga.; On the Sterilization of Cutting Instruments, by Dr. H. A. Royster, of Raleigh, N. C.; When Shall We Resect in Tuberculous Disease of Joints? by Dr. C. E. Caldwell, of Cincinnati, Ohio; The Clinical Consideration of Tumors, by Dr. W. F. Westmoreland, of Atlanta, Ga.; Personal Experience in the Surgical Treatment of Cancer of the Cecum, by Dr. G. Wiley Broome, of St. Louis, Mo.; Cases in Which Early Diagnosis of Cancer of the Body of the Uterus was Made, by Dr. Rufus B. Hall, of Cincinnati, Ohio; Final Results in X-ray Treatment of Malignant Tumors, by Dr. William B. Coley, of New York; Fibroid Degeneration of the Uterus After Ablation of the Appendages, by Dr. J. Wesley Boveer, of Washington, D. C.; A Contribution to the Origin of Adeno-Myoma of the Uterus, by Dr. J. Whitridge Williams, of Baltimore, Md.; Alexander's Operation, by Dr. Charles P. Noble, of Philadelphia, Pa.; Effects of Suspensio Uteri on Subsequent Pregnancy and Labor, by Dr. Joseph Taber Johnson, of Washington, D. C.; Surgical Treatment of Goitres, by Dr. G. W. Crile, of Cleveland, Ohio; The Management of Acute Perforative Peritonitis, by Dr. J. Garland Sherrill, of Louisville, Ky.; Some Further Advances in Renal Surgery, by Dr. John B. Murphy, of Chicago; Report of a Case of Rupture of the Diaphragm, by Dr. George S. Brown, of Birmingham, Ala.; Typhoid Fever and Appendicitis, by Dr. J. C. Oliver, of Cincinnati, Ohio; Vaginal Cæsarean Section, Report of a Case, by Dr. C. Jeff Miller, of New Orleans, La.; An Unusual Case of Cæsarean Section: Double Vagina, Double Uterus; Pregnancy in One Uterus, Fibroid Preventing Delivery in the Other, by Dr. Geo. Ben Johnson, of Richmond, Va.; Obliteration of Stomach by Caustic, by Dr. S. J. Mixter, of Boston, Mass.; (1) Vesical Diverticula; Report of Four Cases Requiring Operation. (2) The ultimate Results Obtained by Conservative Perineal Prostatectomy in Seventy-five Cases, by Dr. Hugh H. Young, of Baltimore, Md.; A Typical Case of Tuberculous Peritonitis, by Dr. W. P. Manton, of Detroit, Mich.; Pelvic Floor Repairs During the Menopause, by Dr. Joseph Price, of Philadelphia, Pa.; Pelvic Inflammation: A Discussion of Some Moot Questions Relating Thereto, by Dr. L. H. Dunning, of Indianapolis, Ind.; Hematoma of the Ovary, by Dr. Magnus A. Tate, of Cincinnati, Ohio; Tracheotomy for Gunshot Wound of the Trachea, by J. McFadden Gaston, of Atlanta, Ga.; Stypticin in Uterine Bleeding, by Dr. H. J. Boldt, of New York; (1) Encephalo-Meningocele. (2) An Easy Method of Instituting Peritoneal Gauze through the cul-de-sac, by Dr. W. D. Haggard, of Nashville, Tenn.; Title Not Announced (Drainage), by Dr. C. H. Mayo, of Rochester, Minn.; Title Not Announced, by Dr. M. H. Richardson, of Boston, Mass.

The Late Dr. Henry Tuck.—At a stated meeting of the Medical Association of the Greater City of New York, held November 14, a report from the committee appointed to prepare a suitable minute in regard to the death of Dr. Henry Tuck, one of the charter members of the association, was received and adopted. The first part of the report was devoted to a biographical sketch of Dr. Tuck, and the concluding portion was as follows: "Although Dr. Tuck took a very active part in the management of the Life Insurance Company, he always retained his interest in medicine and in the friendships he had formed with members of his profession. He was greatly interested in the Society for the Relief of Widows and Orphans of medical men, and for many years acted as its treasurer; only giving up this position last winter, when failing health compelled him to do so. Those who were intimately connected with Dr. Tuck, both in his business and in his professional life, will always remember him as an unusually competent, faithful and successful man in whatever he undertook. (Signed) John P. Munn, *Chairman;* Richard H. Derby and W. Gill Wylie, *Committee.*

Yellow Fever in Cuba.—Yellow fever has appeared again in Cuba. Four cases have recently been reported through the Marine Hospital Service of the United States. Two of these have been in Punta de Sol, across the bay from Santiago de Cuba, and two in Havana. These have been the first known cases of the disease on the island since it was stamped out by the medical and military authorities of the United States

during the American occupation of the island. The scourge of "yellow jack" has been unknown since early in 1900. Accompanying the reports of the scattered cases at Punta de Sol and Havana come the most disquieting news of a departure of the Cuban government from its plan of following American lines strictly in all the cities regarding sanitation. The streets are no longer cleaned. Safeguards are being dropped. Petty politics has resulted in an almost complete abandonment of the wise course pursued by the Americans, which was followed by the government of President Palma for more than a year after he began his rule.

It is said in official circles in Washington that the Cubans are paving the way for an epidemic of yellow fever, which will subject the entire southern seacoast of the United States to danger, and which may result in the adoption of unusual measures by this country under the Platt amendment. There is a possibility of the adoption of quarantine embargoes against all Cuban seaports, unless quick and radical measures are taken by the government of President Palma to stamp out the disease. Thus far the cases that have been reported from Cuba are believed to have come from Mexico on cattle steamers, with the exception of one, which contracted the disease from one of the Mexican cases.

Boston Societies.—The Boston Medical Library and the Suffolk Branch of the Massachusetts Medical Society have in conjunction arranged a series of meetings for the coming winter, at which papers will be read and a discussion held on certain subjects of general interest, medically and surgically. The first of these meetings was held November 16, at the Medical Library, and the subject of nephritis was there considered.

Dr. W. T. Councilman, of the department of pathology of the Harvard Medical School, first spoke on "Some General Considerations of the Pathology of the Kidney," going over in a brief and concise way; the pathological finding, in the conditions known as acute degenerative, acute glomerular, subacute glomerular, chronic diffuse and chronic intestinal nephritis. He dwelt on the slow development of the kidney, its very large blood supply and its high capillary tension and the part normally played by glomeruli and tubules in eliminating fluids and solids. The various methods of infection, the selective process in regard to certain cells used by various infections, and their results in the kidney as well as changes due to arteriosclerosis and old age were carefully gone over.

Dr. R. C. Cabot then gave a résumé of an investigation, which, for a number of years past, he had been following up on the subject "limitations of our knowledge of renal disease as shown by examination of the urine." In comparing the autopsy reports of renal disease found microscopically after death with the clinical diagnoses vast discrepancies were discovered. For instance, in 21 cases, pathologically found to be acute glomerular nephritis, only five cases were diagnosed as nephritis at all; in 10 subacute cases five were unrecognized, others being spoken of as fever urines; in the more chronic forms there was a better record but here those cases diagnosed had edema, ascites, etc., as aids in distinguishing them. Fifteen out of 17 chronic glomerular cases were correct and two-thirds of the cases of chronic interstitial and arterio sclerosis were born out by the pathologist. On the other hand, cases were found where the urine showed large amounts of albumin and casts of all kinds, while at post mortem the kidneys were quite normal. Dr. Cabot went on to speak of the very slight value of urea estimation as done clinically, and the decrease of our knowledge of urinary examination and of nephritis.

Dr. Edward G. Wood, of the Harvard Medical School, then read a paper on urinary examination, going carefully into the characteristics of urines as regards twenty-four hour amounts, albumin and sediment in the classes of nephritis, spoken of by Dr. Councilman, borne out by his experience.

In the discussion which followed Dr. T. Bergen Ogden took a stand against Dr. Cabot's views, reporting 30 cases in which urinary examination and pathological findings had quite agreed.

OBITUARY.

Dr. Duncan Campbell MacCallum, who for over thirty years was an active teacher in the medical faculty of McGill University, died last week in Montreal at the advanced age of eighty-one years. In 1850 he was graduated M.D. from McGill, and proceeded to England where he spent some time in London, Edinburgh and Dublin, obtaining the degree of M.R.C.S. Returning to Montreal a year later he was appointed a demonstrator of anatomy in McGill, and in 1856 was appointed to the chair of clinical surgery, which he held up to 1860 when he became professor of clinical medicine and professor of medical jurisprudence. In April, 1868, he was appointed professor of Obstetrics and of Diseases of Women and Children, a position he held up to 1883, when he resigned from active teaching. The late Dr. MacCallum was first elected visiting physician to the Montreal General Hospital in 1856.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, November 5.

THE KING AND HIS TAME SURGEON—THE RELATION OF HOSPITALS TO MEDICAL SCHOOLS—LONDON LUNATICS—THE BOWMAN LECTURE.

The exploits of the Russian Fleet in the North Sea have given opportunities for advertisement of which certain pastmasters in the art have not been slow to avail themselves. All the wounded fishermen, with a single exception, are under treatment in the Royal Infirmary at Hull, where they were landed. One man, however, was brought all the way to the metropolis that he might be cared for in the London Hospital. There was not the slightest necessity for this, as far as the patient himself is concerned, but the authorities of the hospital were determined to utilize the occasion. The Chairman of the Committee, Mr. Sydney Holland, a great grandson of Sir Henry Holland, a famous society physician of the earlier part of the last century, has the ear of the Queen, whom he uses as a decoy duck—*pour le bon motif*, of course, as it is all for the greater glory of his hospital. He induced her to send a message to Hull to the effect that a bed was ready in the London Hospital for the reception of a patient. Touched by this manifestation of royal thoughtfulness, the good folk of Hull sent up a poor fellow suffering from a severe compound comminuted fracture of the humerus, together with a wound of the back of the neck, in which fragments of shell were imbedded. As a natural result of the delay and the exhaustion caused by a long railway journey, the man was in a septic condition when he was admitted. But what is that to the honor of being under the direct patronage of the Queen and of being visited by Sir Frederick Treves at the special request of the King, who has deigned to express his

interest in the case? This condescension on the part of his most gracious majesty has touched the hearts of his loyal subjects, and their feelings will doubtless find expression in contributions to the hospital which is fortunate enough to contain a patient honored by the notice of the sovereign. Treves is supposed to have retired from practice some time ago, but according to the papers he still sees patients. Readers of *Martin Chuzzlewit* will remember Mr. Montague Tigg's famous conundrum, "When is a man in jail like a man out of jail?" to which that gentleman said no one has found the answer. If the word "practice" be substituted for "jail" I venture to think that an answer has been found by Sir Frederick Treves. A short time ago he was visiting a society lady who had hurt her leg; now he signs bulletins about the Prime Minister, who is said to have a small clot in a superficial vein in his leg. The truth would seem to be that Treves is kept hanging about the King, who sends him to look after people in whom he happens to be specially interested, whether it be a former Egeria, a victim of Russian "Captains Courageous," or a Minister of State. To a man of ordinary self-respect the position appears scarcely dignified; but men in this country will stoop to pick a new title or even a fresh decoration out of the gutter. When peers of the realm do not disdain to play the part of flunkeys at Court and high-born maidens strive for the privilege of acting as lady's maids, it is perhaps not surprising that doctors, whom Society looks upon as a lower order of creation, should be content to be treated by the monarch as servants. Some members of our noble profession have, it is well known, been proud to play the part of Sir Pandarus of Troy for royal personages. For centuries the surgeons to the Kings of France rejoiced in the title of valet. Edward VII. is keeping up the tradition of kingship by having at hand a tame surgeon, by means of whom he can display the vicarious benevolence which is a cheap way of earning popularity.

For years past, Mr. Stephen Coleridge, the leader of one corps of the antivivisection army, has brought charges against the London hospitals of diverting money subscribed by the public for the relief of the sick poor to the maintenance of the medical schools attached to many of them. He alleges that large sums are contributed out of the hospital funds to be used for purposes of medical education. He contends that "the money sent by subscribers to hospitals direct and to King Edward's Hospital Fund, is not given in order to afford medical students an education, partly defrayed by the charitable, nor is it given to enlarge the emoluments of lecturers in schools, nor is it given to buy animals for vivisection and instruments and apparatus with which to dissect them alive." Mr. Coleridge knows perfectly well that animals are not dissected alive, but he has made these reckless statements so often that it is likely enough he now believes them. George IV. used after dinner to relate with thrilling detail how he headed a cavalry charge at the Battle of Waterloo. He told the story so often that he at last came to believe it, and on one occasion even appealed for confirmation to the Duke of Wellington, who answered with admirable tact, "I have heard your Majesty say so." King George's laurels were won in far different fields, and Mr. Coleridge is, I believe, like Werther, a moral man, but there is evidently a strong psychological resemblance between them. In regard to the charge of diversion of funds, it is true that some of the hospitals make annual payments to the schools, but it has been shown over and over again that these payments are for value received in the form of services rendered to the hospitals by the medical staff, who are, for the most part, teachers in the schools, and by the students who do much of the actual ministration to the sick. It would doubtless be well for other reasons if the hospital schools were merged in the University of London, which has no organic connection with any hospital. This, besides other greater advantages, would have the effect of knocking the bottom out of a foolish and dishonest agitation. In the meantime the whole question of the financial relations between the hospitals and the schools is to be carefully investigated by a committee consisting of Lord Welby, a great financial authority; Lord Edward Fry, an ex-Lord Justice, and Archbishop of Stepney. The Committee is to consider and report: "(1) Whether any, and if any, how much, money given or subscribed for the relief of the sick poor to the twelve London hospitals having medical schools, is contributed, directly or indirectly, by those hospitals, or any of them, for the maintenance of medical education. (2) Whether any direct or indirect return for such contributions (if any) is received by the hospitals from their medical schools, and, if so, whether such return is equivalent to the amount of the contributions. (3) Whether, in the event of the committee finding that any hospital contributes to its medical school a sum in excess of the return it receives from the medical school, there are any special considerations advanced in justification of such expenditure, or any general considerations which would apply to all hospitals having medical schools." It is to be hoped that the result of the inquiry will be to suppress abuses, if any are found to exist, and effectually to stop the mouth of calumny.

The London County Council has control of all the public lunatic asylums, and of all pauper lunatics in licensed houses, workhouses, etc., in the County of Middlesex. There are eight asylums and one Epileptic Colony within the area of its jurisdiction. The number of lunatics under its charge was, according to its annual report, which has recently been issued, on January 1, of the present year, 17,592 (7,555 males and 10,037 females); this is an increase of 327 (236 males and 91 females) as compared with the foregoing year. In addition to these there were 6,356 patients (3,068 males and 3,288 females) in the imbecile asylums of the Metropolitan Asylums Board, making the total number of lunatics of all classes (exclusive of private patients and those chargeable to the Prison Commissioners), 23,948, as against 22,952 on January 1, 1903. The total increase of 996 lunatics is the largest annual increase the Council has ever had to record. The number of cases admitted to the London County Asylums during the year ended December 31, 1903, was 4,502, the number of patients discharged recovered was 1,352, being a trifle over 30 per cent. on the total admissions, a little over eight per cent. on the average number resident, and nearly 6½ per cent. on the total number under treatment. The number of deaths was 1,485, a percentage of 7.05 on the total number resident as compared with 7.65 in 1902. The County Council is very proud of its asylums, and as far as size and appearance are concerned it has reason to be so. An American physi-

cian who visited Claybury Asylum not long ago asked, when he saw the ballroom, if it was not Buckingham Palace he was being shown. A vast amount of money has been wasted in palatial buildings with accommodation for two or three thousand patients; but although these huge establishments impress the unthinking public, they make the judicious grieve. As places of treatment for brain-sick people they show results greatly inferior to those of small asylums; as places of scientific observation they are simply failures. The medical staff is utterly insufficient even if the Superintendent and his assistants could give their whole time to their patients; but if a house physician in a general hospital finds it all he can do to record his observations of fifty patients, what kind of clinical study can be expected of a man who has charge of five hundred? In addition to this a heavy burden of clerical duty is put on the shoulders of the unfortunate medical officer, and this he must do lest a worse thing befall him. The result is what might be anticipated. The medical work is scamped in a manner that makes the records useless and misleading, even when they are not purely imaginative, while the value of the figures may be estimated in accordance with the degrees of comparison "Lies, d—d lies, statistics." Of the quality of the clinical records some idea may be formed from the fact that medical officers often keep no notes at all, but hurriedly fill in their books more or less at random when a visit of the Commissioners in Lunacy is impending. A man in such an emergency has been known in his haste to take the post-mortem register instead of the admission book and describe patients as "in fair general health," who were not only dead but anatomized. Compared with this such statements as "No history or sign of syphilis" in a case where the traces of the disease were writ large all over the body, or "No evidence of tuberculosis" in another where there was a cavity in the lung into which a man could put his fist, are trifling errors. And it is to be feared that our lunacy statistics are, to a large extent, made up of such material. Under the present system medical officers are selected more for their social and athletic accomplishments than for their scientific knowledge. Comparatively few of the assistants have any prospect of rising to the post of Superintendent; hence in a professional sense they soon run to seed. If a man of any capacity does stray into the service he soon finds that ardor in the pursuit of knowledge or keenness in the discharge of his medical duties is too likely to bring him into conflict with his official chief or his Committee, perhaps with both. Original work is not encouraged, and the most enthusiastic student after a time loses heart and sinks into a groove of routine. Hence little use is made for the furtherance of knowledge of the abundant material in the asylums. Things are no more satisfactory from the patient's point of view. The indiscriminate herding together of cases of all kinds and degrees of insanity in vast crowds minimizes the chance of recovery in curable cases. For years the establishment of hospitals for the insane staffed by men equal in professional standing to the physicians and surgeons of general hospitals has been urged on the Council. This would make it possible to treat a number of cases in the early stage without marking them with the social stigma of declared lunacy. It would also give opportunities for the scientific study of insanity, such as do not at present exist in this country. The London County Council is entitled to the credit of having made provision for scientific research in the well-equipped laboratory at Claybury, where excellent work is done by Dr. F. W. Mott. But the advantages of the laboratory are in great measure nullified by its distance from London. If it were transferred to London, it would doubtless become a center of neuropathological research. There is a powerful party in the Council, however, which is jealous of scientific progress, and so far they have successfully resisted this proposal. But, if disposed to be obstructive in regard to research, the Council seems to be inclined to a forward movement in the direction of treatment. Some time ago a "hospital villa" in connection with the Bexley Health Asylum was opened for the reception of female patients. There they are kept till a diagnosis has been made. Cases in which there appears to be no chance of recovery are then transferred to the main building. Those of a more hopeful character are kept in the villa till convalescence is established, when they are transferred to a convalescent villa and eventually discharged. The plan has worked successfully, few of the new cases needing to be admitted to the main building at all. So far it has been tried only in the case of female patients, but the results have been so encouraging that a "hospital villa," for men is about to be built. On the whole, though our method of dealing with lunatics stands urgently in need of reform, signs are not wanting that a better day is about to dawn.

On November 3 Dr. Mott delivered the Bowman Lecture before the Ophthalmological Society. The audience was unprecedentedly large, though it is to be feared that most of them followed the distinguished lecturer non *passibus æquis*. His discourse was, as Mark Twain said of the story of Jonah and the whale, "interesting but tough." In addition to the members of the society there were histological and psychological experts, but the histologists were perplexed by the psychology, while the psychologists found themselves at sea in the boundless deep of histological details over which Dr. Mott sailed serenely. The lecture embodied the results of original work on the Evolution of the Visual Cortex in Mammals. It was pointed out that there was a correlation of structure and function which was exhibited by progressive complexity of cell lamination of the visual cortex in mammals from Insectivora to Primates. The more, said Dr. Mott, the animal depends on vision as a directive faculty in its preservation, the more complex is the structure. The transition of uniocular panoramic to perfect binocular stereoscopic vision shows successive stages in the number of direct fibers until in the primates there is semi-decussation and, as far as his observations go, this may be correlated with a progressive development in the layer of higher associational pyramidal cells lying above the layer of granules. The progressive evolution of vision as a directive faculty is simultaneous with a motor adaptation, especially related to the mode of feeding and defence, rather than to a particular species. Carnivorous animals, especially cats, therefore have their eyes set forward, abundant direct fibers, and good binocular vision to enable them to seize their rapidly moving prey with their teeth or paw. Better motor adaptation, as Sherrington has independently suggested from his flicker observations, is probably the essential cause of the direct path of the optic fibers and binocular vision. It is, however, in the primates

that we have semi-decussation of the optic fibers, a muscular lutea, eye-movements in all directions independent of head movements, associated head, eye and hand movements and perfect binocular stereoscopic vision, associated with the hand, which, in the apes, becomes the principal executive agent in the procuring of food, defence and flight. Visual images are now always associated with impressions of the exploring hand and the ideas of form, substance, extension and qualities of objects are the complex of the visual and tactile kinesthetic images and capable of endles variations. This we may connect with an occipital lobe, a line of Gennari visible to the naked eye, a deep layer of pyramids with a double layer of granules in the visuo-sensory striate area. Even more important than this is the appearance of a definite associational zone, in which there is a much greater depth of pyramidal cells, the third layer of which is characterized by very large pyramids serving as higher complex association neurons between the visual cortex and the auditory and tactile motor areas. As we rise in the scale of primates this associational zone increases with the more perfect specialization of the forelimbs for manipulation and the erect posture and this we may correlate with the increase in area of the associational or visuo-psychic zone and the pushing back and infolding of the striate visuosensory cortex so that in man it comes to occupy the infolded calcarine region of the mesial surface, although some types still preserve the anthropoidal character. It is possible that the same causes may give rise to the shifting forward of the anterior motor eye centers. Dr. Mott added that the extensive observations, as yet unpublished, of his assistant, Dr. Watson, on the visual cortex, showed that the pyramidal layer was concerned with higher associative memory and educability. Concerning this view the lecturer endeavored to show that a most important factor in educability is a storage capacity in associative memory of the combinations of stereoscopic visual images with varied complex and refined tactile motor experiences which arriving at its fullest perfection in the primates, progressively develops in successive stages from the ape to man, coincidently with the specialization of the hand and the erect posture, until by reciprocal interaction of the directive and executive faculties the hand becomes the instrument of the mind; and that this progressive evolution may be correlated with anatomical changes in the convolutional pattern of the brain and increase in numbers and complexity of the pyramidal system of higher association neurones.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held October 26, 1901.

The President, Dr. Roland G. Curtin, in the Chair.

Case of Typhoid Fever Complicated by Appendicitis.—Dr. Moses Behrend read this paper. The patient contracted typhoid fever of a rather severe type; in the third week of the disease he developed symptoms of perforation which at operation were found to be those of appendicitis. He recovered for an operation of the latter; ten days afterwards he was tapped for pleurisy with effusion. About fourteen days after this he developed pneumothorax. The patient made a fine recovery.

Dr. L. J. Hammond, in the discussion, thought that the case illustrated the fact now generally admitted that appendicitis occurring in the course of typhoid fever is entirely coincident, and in no way connected with the typhoid process; and that the majority of cases of appendicitis occurring in the course of the typhoid fever are recurrent attacks. Given a case of typhoid fever with the early symptoms of pain, rigidity and other symptoms of appendicitis one should suspect the presence of a large amount of adhesions; and, if the symptoms are severe, the surgeon is justified in operating at once. The removal of the appendix, breaking up of adhesions and liberation of the coil of intestines will lessen the possibility of typhoid perforation.

Dr. W. H. Teller thought that, notwithstanding the fact that the mucous coat presented all the symptoms of typical catarrhal appendicitis, the condition was that of perforative typhoid with involvement of the peritoneal covering of the appendix by extension and not a case of pure appendicitis.

Dr. J. Allison Scott thought it should be remembered that there are several varieties of inflammation of the appendix in typhoid fever. Reviewing the literature of the perforation of the bowel, and collecting statistics of the hospitals of London and suburbs and of the Pennsylvania Hospital he has found 382 cases of perforation, 17 of which were in the appendix alone and due to ulceration from within. There is another type in which during the course of the typhoid fever, or during the convalescence, acute inflammations of the appendix have been set up but not due to ulceration within the appendix, but from the appendix becoming gangrenous and perforating in the ordinary form of appendicitis. Dr. Scott is inclined to believe that if cases of perforation of the bowel are studied carefully it will be found that the appendix is involved more frequently than is thought.

Dr. Astley P. C. Ashhurst believed that there were several varieties of appendiceal inflammations during typhoid fever. That they could be distinguished by the different symptoms he did not think was possible. In the early stages of typhoid fever there could be seen constant pain, vomiting and a certain amount of shock with rigidity over the appendix. At operation there would be found infiltration of the appendix and an appendicitis, the probability being that these were only typhoid lesions in the appendix. Later on there might be present the same conditions through perforation of ordinary inflammation of the appendix. The inflammation, he believed, would so obscure the typhoid lesions that to distinguish one from the other was hardly possible.

Dr. Behrend, in closing, took exception to Dr. Teller's remark that the case was one of preperforative typhoid fever. He believed it to be one of pure appendicitis; due, he granted, to the extension of the inflammation as a result of typhoid. He considered it a case of pure typhoid fever and not such as Dr. Teller stated As interesting facts connected with the case, Dr. Behrend stated that of five nurses connected with the case, one contracted typhoid fever, another appendicitis and died from peritonitis. The patient's wife contracted typhoid fever and recovered. The nurse who contracted typhoid fever also recovered.

The Trend of Modern Prescription Writing.—Dr. M. Clayton Thrush considered this subject both from the standpoint of the physician and the pharmacist. One thousand prescriptions were examined and criticized from the standpoint of incompatibility, whether chemical, therapeutical or pharmaceutical. The number of ingredients used were classified in groups. The

number in which the metric system was employed was also considered and finally the prescriptions were classified acording to the manner of writing, terminations and phraseology being included. These various headings were elaborated upon and improvements suggested. The prescriptions containing only official preparations were classified, also those in which proprietary preparations were used.

The Relation of the Physician to the Bureau of Health.—Dr. S. W. Newmayer said that in the word cooperation were gathered all the duties of the physician to the Bureau of Health. There should be no need of legally calling some physicians to account for failure to report cases of contagion in order to set an example to other physicians. He made a plea for more accurate and earlier diagnosis by the use of laboratory methods, and for a postgraduate course in the clinical diagnosis of the more common communicable diseases. The Bureau of Health, he believed, should have under its supervision a series of lectures and demonstrations by competent teachers, which physicians should be invited to attend. It should be compulsory for all medical students to attend lectures on contagious diseases and to see cases in the city hospital. There should be given to each graduating class one or more lectures on the duties of a physician to the Bureau of Health, explaining what diseases to report and the best means to protect the public. To lessen the mortality from tuberculosis there should be a practical and concerted plan of education, as well as a report of cases of tuberculosis. Every physician should spare a little of his time in imparting the principles of domestic hygiene to those to whom he is called in his daily work. The consideration of simple lessons on contagious diseases should be borne in mind by physicians having the revision of school text-books. To lessen the infant mortality, largely caused by impure milk and improper food, the physician, trained nurse and even the public should be taught a few practical and simple tests for impurities in milk.

Dr. Edward Martin, Director of Public Health, said that the desire of the Bureau of Health was to help the medical profession, to act as its agent, and not as a foreign intervention, that the Bureau asked the help of the profession and was ready to give in return its assistance. He referred to the corps of young men insructed in the work, every man of which has been a hospital resident, had had a special course in contagious diseases, and in other directions been fitted for the work. Dr. Martin said: "You cannot teach all men tact and judgment; you can make many men wise, but you cannot make all men sensible." The underlying spirit of every man in the corps, however, he said, was to help, and to stand by the profession, and not to interfere. With the help of the profession the whole city work would be a success.

Dr. I. Valentine Levi said that the fact that the Board of Health should carry out the disinfection, unless the physician obtain special permission to do so, had been the source of much trouble between the medical inspector and the doctor. The family physician would tell the family to burn some sulphur and that the Board of Health would not need to do anything, and when the medical inspector would appear and insist that the house be disinfected, he would get all kinds of beautiful appellations. In one instance the medical inspector was reported to the central office as doing everything possible against the medical profession. He felt that the physician should tell the patients that the house must be disinfected by the Board of Health, unless he orders otherwise.

Dr. S. Solis Cohen regarded as important the question of what was to be done with patients suspected of having diphtheria, until a culture was made. He believed it the duty of the physician, whether in his office or in the dispensary, to disinfect the throat promptly when there is any question in diagnosis.

Concerning the action of the Board of Health and its inspectors, his own experience has been that there need be no trouble, if both sides were willing to act, as human beings who recognize their own liabilities to mistake, ought to be willing to act. Occasionally an officious or tactless inspector had done or said something in the household of a patient to which he felt he could take reasonable objection; but, he had always found the communication with the superiors of this tactless or officious inspector had been the means of having him so instructed that he would not repeat the error elsewhere. That, he believed to be one of the factors in the relation between the physician and the Board of Health that each physician would well cultivate, being prompt and unsparing in the direct report to the chiefs of the Bureau of Health of any dereliction, or seeming offence, on the part of their inspectors. Sometimes it would be found that the physicians had been misinformed by the patients. He felt that the Bureau of Health was deserving of all the support and advice that could be given by the medical profession.

Dr. Jay F. Schamberg agreed with Dr. Cohen that there were many instances in which both patients and physicians were misrepresented. He knew that the average ability of the members of the board of medical inspectors in the detection of contagious diseases was of a very creditable standard, and bound to increase. He believed that the medical profession had full confidence in the Bureau of Health, and that the subject should be approached with a little more charity on both sides.

CHICAGO ACADEMY OF MEDICINE.

Regular Meeting, October 14, 1904.

The President, Wm. H. Wilder, M.D., in the Chair.

Chorea Insaniens.—Dr. Daniel R. Brower stated that the insanity of chorea, particularly the insanity of Sydenham's chorea, was a very infrequent condition. In Huntingdon's chorea there was progressive mental deterioration eventually leading to dementia. The most important form the practitioner had to contend with was Sydenham's chorea. In his cases for the last dozen years there was about one case of chorea insaniens in every two hundred. In two-thirds of the cases of Sydenham's chorea mental disturbance occured. Chorea was a brain disease, and mental peculiarity was conspicuous. As a rule, the mental state was one of confusion. Accompanying the confused mental condition there were maniacal and depressing states. A very large proportion of the cases he had seen belonged to the maniacal type. The depressive confusional form of insanity, which was the outgrowth of chorea, was much less common. The last case he saw was a young woman of twenty-three years, in whom the maniacal manifestation was very pronounced. She had had chorea since she suffered from a fright two months previously. When he saw her the case was a well-marked one of the maniacal type of acute confusional insanity. Sometimes there was a stuporous state; but usually it was the maniacal confusional type, or the depressing confusional type. Many years ago he witnessed a post-mortem on a case of chorea insaniens of the Sydenham type in a girl,

nineteen years of age, in whom there were found most striking pathological conditions. Among them were minute multiple emboli in the striate arteries. The patient had an endocarditis. Whenever he had the opportunity of getting hold of a case in the beginning, he insisted upon rest for the first week or ten days, no matter how mild the case. The child should have as near absolute rest as possible. It should be put to bed, given all the playthings possible and separated to the utmost extent from the family generally. Rest and isolation were the foundation stones upon which any treatment of chorea should be built to prevent the development of more serious mental symptoms. The best single remedy for chorea was arsenic. Fowler's solution was the best preparation in the majority of cases. When the arsenates did not agree with the child, it should be given sodii arsenitis. Arsenical preparations must be pushed in order to bring about curative results in chorea. Arsenic should be given until the approach of toxic symptoms, as curative effects were just a little short of toxic effects. The next best remedy was cimicifuga. Frequently he combined the two, the fluid extract of cimicifuga, giving it in gradually increasing doses, until he got to its physiological effect, and in this way it gave satisfactory results when arsenic alone failed. He had found cimicifuga beneficial in the Sydenham chorea of girls about he menstrual period. Furthermore, one should not forget the diet, as these children were below par in nutrition. They should be given digestible, easily assimilable foods in the greatest possible abundance. He would put a child to bed for a week, sometimes two weeks, and then gradually relax the rest cure. He would have these patients go to bed early and have breakfast in bed. During the remainder of the day they should go outdoors and play. This would be about the second week, and if he found no letting up in the choreic movements under this treatment, he would try static electricity. There was no question as to the sedative effects of positive insulation on the insulated stool of a well-working static machine. The prognosis of chorea insaniens was not bad. Some patients would go on to permanent insanity, and some would die; but the latter proportion would be small.

Dr. Frank X. Walls reported the case of a woman, about eight months pregnant, who, in 1891, developed chorea in its gravest form. She was admitted to the Cook County Hospital, and after a few days there, on every treatment he could think of to relieve her, she died. A post-mortem examination was made, and endocarditis and some congestion in the brain were found. Chorea was merely a manifestation of a condition that might exist in a variety of pathological processes. It was the manifestation of a neural malnutrition, an intoxication or infection, and showing itself in bizarre, and incoordinate muscular movements. There was usually a mental picture in a patient suffering from this malnutrition and intoxication that showed itself in neural and mental phases. These cases varied clinically from the mildest to the severest types. Many of them were relegated to an insane asylum as incurable. In a large number of cases there seemed to be a close association between those of chorea and some infection. In cases of chorea evidence of infection, such as elevation of temperature, and the localization of distinctive inflammatory conditions in certain organs, as the endocardium primarily, the joints sometimes, and may be the brain, often existed. It was a remarkable thing, yet nevertheless true, that in no other condition did one find as complicating endocarditis in cases of acute rheumatism as in chorea. More endocarditis accompanied this clinical picture than in any other diseases. Of a series of cases recently investigated in the Leipsic Hospital, there were over 79 cases of chorea that showed endocarditis clinically. This agreed with the experience of Osler. In a large number of cases that attended Osler's clinic, evidences of endocarditis were found years after the chorea had been recovered from. Not alone did chorea occur with acute articular rheumatism, but it often followed influenzal rheumatism, tonsillitis, and particularly a type of which he had seen a number of cases since his attention was called to it, severe gastrointestinal disturbances, especially such as suggest appendicitis. The tonsils were the seat of entrance of infection into the body, and rheumatism was not an infrequent condition following tonsillitis. A little girl presented herself a year ago, with an attack of severe nervousness, very much like the chorciform movements, with pain and gastrointestinal symptoms, vomiting and joint complications. After one week of illness the pain in her abdomen became so severe that she was forced to go to bed, although previous to that she was walking about. The child was in bed a week, during which the abdomen was very much swollen. She vomited offensive matter that seemed fecal. During all this time there was dynamic obstruction of the bowel. He saw the child a year after, and she had a marked endocarditis. Her elbows and knees were partially anchylosed, but the mental symptoms had cleared up almost entirely. This child probably had had appendicitis. A physician at the time made such a diagnosis, with rupture, peritonitis, and systemic infection, which produced multiple joint complications. Probably this irritation in the brain had resulted in chorea.

In any given case of chorea, the etiological factor or factors should be considered, and each case should be treated individually. He would not subscribe to the administration of any remedy, unless there was a distinct individual indication for its administration. Treatment should be individual.

Dr. Henry T. Byford, when he was engaged in general practice, had a great deal to do with children. He treated a number of cases and looked upon them from a more simple standpoint than was done now. His treatment then was iron, laxatives, and if the case was more or less acute he gave a few doses of chloral from time to time, together with rest treatment. He guarded against the giving of food that was liable to disturb the bowel and digestion, and regulated the diet of these patients. In these cases a great deal of trouble came from the alimentary canal which was largely reflex. Supposing there was heart trouble or disease of the serous membrane due to toxins, what produced the toxins? Supposing it came from the alimentary canal by way of the abdominal tonsil, so-called, when that occurred there was usually intestinal disorder, which irritated and rendered abnormal the latty tissues about the appendix, a more central absorption of poisons was liable at the same time to produce reflex symptoms. He thought chloral did much good, although he would not continue its use until it produced any debilitating effect. Iron did good in fortifying resistance against irritation in the alimentary canal. Convulsions arose from irri-

tation of the alimentary canal in children. In gouty individuals contractures of limbs could be relieved by laxatives given quite a while.

Dr. William F. Waugh mentioned the case of a young man who, soon after starting in school, developed choreic symptoms. He was quite positive that the young man's eyes were troubling him, and therefore sent him to a very capable ophthalmologist, who examined the eyes carefully and reported that there was nothing the matter with them. So sure was the speaker that the patient's eyes were affected from peristent use in school, that he sent him to another ophthalmologist, who found the eyes affected, fitted them with glasses, shortly after which the choreic symptoms subsided. Since that time, when the choreic symptoms reappeared, he had charged the young man with neglect to wear his glasses, and found it had always been the case. Here the trouble with accommodation was undoubtedly the cause of chorea. He mentioned the case of a child who was about to be sent to an institution as an instance of total moral depravity, but a rhinologist fortunately removed the adenoids which the child had, and the patient developed a sweet disposition. He emphasized the importance of paying attention to elimination and to the regularity of the exertions.

Dr. James G. Kiernan said that chorea insaniens was a term applied by the Germans to a type of chorea in which there were manifestations of the acute confusional type of insanity, very frequently without emotional basis. This, as a rule, was an expression of a systemic state of exhaustion, that produced the chorea, rather than a condition secondary to chorea. That chorea might produce insanity there was no doubt. Mental agitation of the patient would prove a sufficient breakdown for inhibitions to a motor direction, and in the same way breakdown in a psycho-motor direction. Of the cases cited by Osler, two were striking as indicating, not as Osler claimed, the deep-seated, distinct nosological character of chorea, but that this systemic adynamia might produce chorea and a changed mental state. One was a marked systemic disturbance; the other was the secondary stage of syphilis. The mental conditions of the secondary stage of syphilis, as the speaker pointed out nearly one-quarter of a century ago, and which had since been corrborated by Regis and others were essentially acute confusional states. There was a state closely allied to the acute confusional conditions, so far as the mental symptoms were concerned: so-called Bell's disease, typhomania of some authors, the delirium acutum of the Germans, and delirium grave of Spitzka. In the acute confusional states, except where secondary to conditions allied to rheumatism, etc., lesions might be absent. There were no pathological findings, microscopic or macroscopic. In delirium acutum, or delirium grave, there was well-marked, clearly distinguishable meningoencephalitis, with equally decided and destructive microscopic changes. He did not believe with Meyer that delirium grave or confusional insanity was an expression, strictly speaking, of this state, hut that this state was an extension consequent on the circulatory disturbances of what might have been an acute confusional state. He was much impressed with this in the many necropsies made at a time when Dr. E. C. Spitzka and he were collecting somatic material in cases of insanity. He was struck with the absence of actual lesions in certain cases which did not pass beyond the acute confusional state as contrasted with the demonstrable presence of lesions in this state. This was twenty years ago. When the germ theory of disease began to dominate medical thought, he was strongly of the opinion that in all probability typhomania or delirium grave was a germ condition. Tests by Koch's law in Italy, Scandinavian countries, Germany and the United States had signally failed to demonstrate any germ factor. Furthermore, the condition may come on as one of the so-called meningitides. It would come on after school strain and a number of conditions of that kind. It might also come on from the perturbations which occur in railway accidents and similar conditions. Of that class he had seen two cases, which died in the Cook County Insane Hospital. In that instance, as in a similar one, that threatened to be the subject of litigation, the early diagnosis was chorea. Mental symptoms grew deeper and deeper, then there followed an extremely marked, semi-stuporous delirium, in which the control of the sphincters was lost. There was rise of temperature, and then death. Autopsy showed very marked and decided evidences of delirium grave. In a similar case in Chicago there had been an accident on the Northwestern "L" road, in consequence of a collision. The girl was removed to her home in what appeared to be a condition of chorea. A diagnosis of chorea was made by the attending physician. Changes went on the case passing from chorea simplex to a confusional mental state, which grew deeper and deeper until she finally died. An autopsy was made by the coroner, who made the pathological diagnosis of acute cerebral meningitis, which was all he was entitled to make from the findings. Fatal termination had not been suspected. The question was raised whether this condition was due to the accident or some outside cause. There was a question raised which had arisen in this State ever since the Braun *vs.* Craven case was brought up, in which it was decided that simple fright is not sufficient. The question of physical impact was brought up and argued. The qu stion was incidentally raised by the railroad company as to whether the trouble was not due to secondary infection. The only element in the girl's history which bore on secondary infection was the existence of a gum-boil that had been treated by the family practitioner, from which she had made a recovery without showing the slightest effect. The question of physical impact was discussed a good deal. In consequence the case was never taken up in the courts because the amount offered by the railroad company would have been all that could have been realized by litigation under the old law as regards responsibility for death. In this case there was very little doubt left from the evidence as to the direct determining influence of traumatism. It seemed to him a constitutional factor, rather than a local one, played a large part in many of these cases. He was strongly opposed to the treatment of cases of chorea insaniens in insane hospitals. The insane hospital had its value, but the vast majority of cases of confusional mental states could recover excellently under general hospital treatment. They should be removed from their accustomed environment. A large number of cases were benefited by arsenic, and arsenic should be physiologically pushed. As nearly all these states depended upon weakness, or disordered inhibitions, they were benefited by those agents that

acted as sedatives rather than stimulants. Furthermore, strychnine in small doses was frequently an excellent sedative. It gave a certain amount of rest that was not attained by other agents.

Dr. William L. Baum had, at the present time, a child suffering from whooping-cough that had developed choreic symptoms. He looked upon the disease as a symptom-complex, which might be due to a large number of different causes, as syphilis, toxemia, rheumatism, etc. Regarding the use of arsenic and pushing it to the constitutional limit, every year there occurred increasingly large number of cases of arsenical neuritis. There were also cases of paralysis following administration of arsenic. A few days ago he saw a case of paralysis of the facial nerve occurring in an individual to whom arsenic had been given for a period of years, and carried up to the constitutional limit. Some time ago the patient complained during the administration of arsenic of extreme pains occurring in the region of the Gasserian ganglion. All of the symptoms were found which are present in the ordinary arsenical neuritis. There was considerable pressure in this region, and complete motor paralysis developed on one side of the face from which recovery was extremely slow.

Dr. C. S. N. Hallberg asked if Dr. Brower had had any experience with the hypodermic administration of sodium arsenate solution. Dr. Moyer had used it quite extensively for several years, and spoke strongly in favor not only of its hypodermic use of it, but likewise of the sodium arsenate as against the arsenite, the form of arsenic represented in Fowler's solution. Evidently there was much less danger of untoward effects from the arsenate of sodium than there was from the arsenite. He also asked whether there was any difference in value of the preparations from the green cimicifuga or dried. This question had come up different times in the revision of the pharmacopœia. Some therapeutists argued that cimicifuga should not be admitted to the pharmacopœia, because only preparations of the green or fresh root were of value. That would be inadmissible in the pharmacopœia, and it would not be proper to admit a dry drug, or preparations of it.

Mr. V. G. Gallagher (of the Chicago Bar) stated many phases of the subject that could be discussed. As to the right to recover damages for chorea and kindred affections, he had this to say: The question as to whether injuries resulting from fright and terror would form a recoverable basis in an action at law had been the subject of much discussion in courts of law not only in Illinois, but in all States. As a rule, as gathered from the conclusions arrived at by various authorities, there was one class of cases in which damages could not be placed on recovery. The first class was where the injury was brought about purely by fright and terror, but physical impact was entirely absent. In those cases, while there was a general rule of law in reference to actions predicated upon negligence, there was no liability except for such consequences as were usually ordinarily likely to emanate from the act complained of, and in determining whether the consequences were usual and ordinary, the individual would be treated as a general individual, and not as a special one. That is to say, the party claiming redress would be considered by the law as a healthy individual from the time the alleged cause of action arose, and not as a sickly one, so that if the acts complained of, which were alleged to produce injuries, were not such as would produce injuries of the character complained of, in an ordinary healthy individual, whatever that might be, there could be no recovery for the injury regardless of how severe it might be.

Before taking up the other class, one of the principal cases to rely on for a ruling was the one Dr. Kiernan had just cited (Braun *vs.* Craven). That was a case where the defendant (a minister) called at the house of the plaintiff's sister, the sister being a tenant of Craven's, and finding the door open he walked through the house to her room, where the patient was sitting on the floor assisting her sister in packing preparatory to moving, and suddenly asked what she was doing, following that interrogation with many gesticulations, and statements to the effect that he would not allow them to move, and would have a constable there in a few minutes, and he was going to have his rent, etc. She alleged that his conduct on that occasion, when she first turned around and saw him standing up, greatly frightened her, particularly his subsequent gesticulations, with the result that she became afflicted with St. Vitus' dance and some other nervous ailments. The trial resulted in a verdict in her favor for $9,000. This was reversed by the Appellate Court, then carried to the Supreme Court, where the Appellate Court was sustained. There were two reasons assigned which he did not think were sound philosophical legal reasons, namely, as a basis of conserving the interests of public policy, damages should not be recoverable in cases in which injuries were claimed to result slowly from fright and terror. Furthermore, dangerous use might be made of such a ruling if injuries were permitted to be made a basis of action where there was no means of measuring the damages.

The second class was one in which the question was whether there was physical impact preceding the nervous conditions. In such cases it had been held, regardless of how slight the impact might be, if nervous troubles followed, that is, including distress and anguish of mind, or excluding everything else, and including only distress and anguish of mind, that compensation might be allowed. The other class is where the intention of the wrongdoer was to inflict mental anguish and distress. The principal cases included in that class would be those of seduction. Where seduction was cause for right of action, which was not he rule in Illinois, except on the theory of loss of service, the parent, guardian or employer in some instances might maintain action against the seducer for the loss of service and slander, etc. In this latter class of cases the recovery was not limited to the actual damage sustained, but purely exemplary damages may be awarded. The intent of the wrongdoer, if possible, must be established, so that the punishment meted out will be commensurate with the injuries. The peculiarity presented by the different rulings consisted in this: In the first instance, while the Supreme Court decision in the Braun versus Craven case might be said to be well taken upon the ruling first rendered by it, namely, the conditions under which this woman was frightened, were not such as would frighten an ordinary healthy individual, and the results claimed to exist were not such as would follow ordinarily, yet, as to the other decision or ruling, that it is against public policy, yet as to the other decision or ruling, that it is against public policy to allow damages which cannot be measured, if re-

covery of damages is allowed for this element in cases where there is an infinitesimal physical impact, so that the major portion of the injury sustained is a nervous one, mental anguish, etc., it is just as easy in such cases to exaggerate and elaborate upon that basis as it would be in cases where the physical impact was entirely absent.

As to the other proposition, he said there was no methodical rule by which damages could be measured in every action brought for personal injuries. The rule of law in all such cases as to how much shall be awarded was left to the sound judgment and discretion of the jury, and their verdict was not interfered with, except where it was manifest they had abused their discretionary power. His advice to physicians was that where they had a patient who was suffering severe mental anguish and other nervous disturbances, or even fright, it would be well for them to devote some of their time to discover some little physical impact, even though it consisted of not more than a concussion caused by an explosion or something of that kind. A German and his wife heard a noise in the basement of their house, and went down there to see if they could discover what it was. The wife lit a match, which was followed by an explosion. There was no physical impact in that case other than that caused by the concussion. This case was taken away from the jury in the trial court on the strength of the decision rendered in the case of Braun *vs.* Craven. The trial court seemed to think that simple fright was shown by the fact that physical impact was absent. The Appellate Court reversed that decision, largely upon the strength of Dr. Kiernan's testimony, who was quoted extensively in the opinion which was rendered.

Dr. Brower, in closing, said that no one recognized the untoward effects of arsenic more than he did. He was glad Dr. Baum called attention to the fact that these effects were due to the long-continued use of arsenic. He did not think any physician was justified in administering doses of arsenic such as he had referred to in any case for long periods of time. If results were not speedily obtained, the remedy should be withdrawn, so that the general principles applying to the treatment which he had enunciated did not contemplate the long-continued use of arsenic in large doses. As to the hypodermic use of arsenic in chorea, he remembered very well Dr. Moyer's paper, but for some reason or other his patients would not submit to the hypodermic use of arsenic. He could not get them to take more than one or two doses. The patients were nervous childdren; they did not like to be hurt, he did not know of any way of giving a hypodermic injection of arsenic without inflicting some pain, unless it be done by cataphoresis, and even then there would be more or less pain. He was free to confess that he had never obtained the results from the hypodermic use of arsenic others had. He did not know whether it was the green or the dry preparation he was using. That cimicifuga had effects upon the ordinary individual and upon certain sick people he was as sure as about any drug. The fluid extract was the preparation he had used.

Why the Quack?—Dr. William F. Waugh read a paper on this subject, which was designed as an inquiry as to how far the medical profession itself was responsible for the resort of the public to irregular and non-professional methods of treatment. He affirmed that quackery had always existed, the tendency to it being innate; but recently the tendency to it seemed greater than ever, so that it seemed the public welcomes any and every avenue of escape from the regulars. Among the possible causes originating in the profession he enumerated the loss of the element of mystery that attracted the superstitious; the desire for novelty; the powerful trend toward operative surgery, which most men dreaded; therapeutic nihilism and pessimism; but more than all else, the loss of confidence in the disinterestedness of the physician's advice. As men suspected that the physician was managing his cases for his own pecuniary benefit rather than for the best interest of the patient, they grew reluctant to entrust themselves to his hands. This phase of commercialism had become the subject of innumerable alleged jokes, and these had a powerful influence in moulding public opinion. The remedy lay in upholding the dignity of the medical profession, in cultivating the highest professional and moral standard, in discouraging this form of humor, and in winning and holding public confidence by deserving it.

BOOK REVIEWS.

A System of Practical Surgery. By Prof. E. von Bergmann, M.D., of Berlin, Prof. P. von Bruns, M.D., of Tübingen, and Prof. J. von Mikulicz, M.D., of Breslau. Volume V. Translated and edited by William T. Bull, M.D., Professor of Surgery, College of Physicians and Surgeons, Columbia University, New York, and Edward M. Foote, M.D., Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York. Surgery of the Pelvis and Genito-Urinary Organs. Lea Brothers & Company, New York and Philadelphia.

With the appearance of the fifth volume this sumptuous work stands completed and may be judged as a whole. A careful consideration of the finished system compels even greater admiration than did the examination of its constituent parts, as they appeared one by one. That so huge an undertaking could be brought to a successful termination with a comparatively small number of months, bears evidence to the untiring industry which all of those concerned must have thrown into their labors, while the careful workmanship visible on every page, is a proof that as much thought as energy was applied to the production of this work.

The present volume covers the important subject of pelvic surgery, including the genito-urinary organs, but not the domain of the gynecologist. The first section is by Steinthal and is devoted to the surgery of the bony pelvis and its arteries. The succeeding chapters on the anus and rectum are anonymous, but the topics in question are treated with admirable thoroughness, and a well-executed colored plate illustrates the normal and diseased mucous membrane of the lower bowel as seen through the proctoscope. The affections of the kidney and ureter are discussed by Schede, in what is the largest subdivision of the volume. Its completeness may be judged of since it covers almost 250 pages. Especial stress is laid on diagnostic measures and the technic of and instruments for, cystoscopy, catheterization of the ureters and segregation of the urine are described and illustrated in most satisfactory fashion. Even the subject of cryoscopy is elaborated, both from the theoretical and practical standpoint. Diseases of the bladder and prostate have been allotted to Nitze and Sonnenburg, and here further information is given regarding cystoscopic methods, together with some

beautifully reproduced photographs taken through this instrument. Körte and Rammstedt are responsible for the section on diseases of the urethra (exclusive of venereal diseases), while the authorship of the succeeding subdivision on the penis is not given. The closing chapters of the book are in the scrotum, testicle, seminal vesicles and vas deferens, and Bramman has written an instructive and practical essay on this branch of genito-urinary surgery.

A word should be said regarding the index, which may make or mar the utility of so extensive a system as this. In the present instance the general index, placed at the end of Vol. V, appears to be above reproach, and should make information contained in any of the volumes readily accessible. The illustrations in this volume are, if anything, superior in execution and interest to those in the preceding books. The plates taken from Taylor's treatise on genito-urinary diseases, are especially beautiful.

It is a pleasure to see an enterprise of such magnitude brought to so happy an issue, and we foresee for the system the popularity and recognition it so richly deserves.

How to Cook for the Sick. By Helena V. Sachse. Second Edition. J. B. Lippincott Co., Philadelphia.

Every physician who has seen his best plans for a patient's recovery brought to naught by improper or poorly cooked food; every nurse who has been at her wits' end to tempt an indifferent appetite or to satisfy safely a capricious one; every invalid who has wearied of the limitations of a diet governed by the terse generalizations of his physician and the anxious but ignorant efforts of his family, all these—and their name is legion—will find welcome assistance in "How to Cook for the Sick." To the physician and trained nurse it will be chiefly valuable in putting into concrete and available form the dietary principles with which they are familiar, but to the uninitiated it will prove positively illuminating.

"What may she eat, Doctor?" asks the home nurse, and the doctor usually mentions a few articles of food of which the patient soon wearies, or else takes refuge in the generalization, such as, "Anything except starchy foods," which leaves the average household as much in the dark as ever. Armed with this book, however, the doctor may indicate at once an appetizing and varied diet, or, on other hand, the amateur nurse may, by its aid, interpret the doctor's general directions in terms of a practical process. The recipes are so simple and carefully expressed that mistakes and uncertainties are eliminated; and the always indispensable index is in this case further developed into a system of classified lists which enables one to turn promptly to the recipe needed, whether "liquid food," "food rich in fat," "invalid's breakfast" or a combination of all three requirements be sought.

All the dishes described sound very attractive, and the healthy reader might be pardoned for a glimmering desire to be in a position to test a few of them.

Simon's Physiological Chemistry. By Charles E. Simon, M.D., late Resident Physician, Johns Hopkins Hospital; author of Simon's Clinical Diagnosis, etc. New (2d) edition. Lea Brothers & Company, New York and Philadelphia.

Year by year the foundations of medicine are being sunk deeper and deeper into the strata of chemical fundamentals, and interpretations of perverted physiological functions are made possible by reason of the acquisition of such substructures in our knowledge.

The importance of the study of physiological chemistry cannot be overstated and it is a pleasure to call attention to this work because it is so well adapted to the giving of just the type of information that can be applied in the problems of medicine.

The author has made his work second to none, and we can recommend it in the highest terms.

Health and Disease in Relation to Marriage and the Married State. Edited by Prof. D. H. Senator and Dr. med. S. Kaminer. Translated by Dr. J. Dulberg. Vol. I. The Rebman Company, New York and London.

This is a most extensive work. Dealing as it does with one of the oldest of social institutions it naturally lays claim to the attention of all.

The diseases incident to the state are here very thoroughly dealt with and the work cannot but help be a mine of useful information.

In this first volume eleven chapters are included. The Hygiene of Marriage, by Prof. M. Gruber, of Munich; Inherited and Congenital Diseases, by Prof. J. Orth, of Berlin; Consanguinity and Marriage, by Prof. F. Kraus, of Berlin; Influence of Climate, Race and Nationality on Marriage, by Dr. W. Havelburg, of Berlin; Sexual Hygiene, by Prof. P. Fürbringer, of Berlin; Menstruation, Pregnancy, Child Bed and Lactation, by Dr. Kossmann, of Berlin; Constitutional Diseases, by Prof. H. Senator, of Berlin; Diseases of the Blood, by Prof. H. Rosin, of Berlin; Diseases of the Vascular System, by Prof. E. v. Leyden and Dr. W. Wolf, of Berlin; Diseases of the Respiratory Organs, by Dr. S. Kaminer, of Berlin; Diseases of the Digestive Organs, by Prof. E. A. Ewald, of Berlin, and Renal Diseases, by Dr. P. F. Richter, of Berlin.

In this ambitious program the authors have frequently strayed from the strict interpretation of their subject, but apart from this padding, as it were, the work is one to be commended.

A Text-Book of Pathology. By Joseph McFarland, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College of Philadelphia; Pathologist to the Medico-Chirurgical Hospital, Philadelphia. W. B. Saunders & Co., Philadelphia, New York and London.

This is truly an excellent text-book, particularly for students and practitioners of some years' standing, who have grown somewhat rusty, can benefit greatly from this recent presentation of the subject.

The work is a large one; it is no book for play-time—it is solid meat and over 800 pages of it. We can commend the setting. The illustrations are numerous and are exceptionally good. The entire book is attractive. The text is modern and we commend it to our readers as a useful reference book.

Kirke's Handbook of Physiology. Revised by Frederick C. Busch, B.S., M.D., Professor of Physiology, Medical Department, University of Buffalo. Fifth American Revision. William Wood & Company, New York.

Kirke's handbook has for a number of years held its place in our medical schools because of the rare ability of the author to compress within a reasonable size the many essential facts of physiology and yet not outrage the theories, nor lose to the student the general perspective.

In a manner thoroughly in line with the original thought of the author, Dr. Busch has shown himself able to do the same thing, and we are glad to welcome the fifth edition, and predict for it a speedy successor in the shape of a new sixth edition.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 85. NEW YORK, SATURDAY, DECEMBER 3, 1904. NO. 23.

ORIGINAL ARTICLES.

SECOND NOTE RELATIVE TO THE MORE EFFICIENT UTILIZATION OF THE SPARK-GAP RADIATIONS.

BY HENRY G. PIFFARD, M.D., LL.D.,

OF NEW YORK;

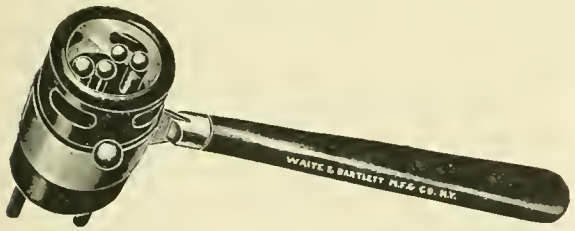
EMERITUS PROFESSOR OF DERMATOLOGY, NEW YORK UNIVERSITY; CONSULTING SURGEON TO THE CITY HOSPITAL, ETC.

I.

IN the June number of the *Journal of Cutaneous Diseases* I published a "Preliminary Note" on the above topic in which I stated that I had discovered some new "rays" given out by my "ultra-violet" condenser spark-gap lamp. (Fig. 1.)

This lamp is furnished in front with a thin quartz plate which is transparent to ultra-violet rays, while glass is opaque to them. If the face of the lamp with the quartz *in situ* be applied to a piece of photographic paper (Solio) and the

Fig. 1.



The author's ultra-violet ray lamp.

lamp actuated by a suitable coil, a strong impression will be made on the paper in about thirty seconds. If the experiment be repeated with the *quartz removed*, the result is substantially the same.

Ultra-violet rays, as is well known, will discharge an electroscope if charged *negatively* but *not* if charged *positively*.

On trial I found that the lamp with the quartz in front discharged the *negative* electroscope in about twenty seconds, but with the quartz *removed* discharged it instantly; that is within less than one second. I found further that the radiations from the unobstructed spark would discharge an electroscope charged *positively*.

It was clear from this that in addition to the ultra-violet rays we were dealing with another class of radiations that only slightly affected the photographic plate, but acted very energetically on the electroscope.

In default of any means of determining the exact nature of these radiations I assumed that they were negative electrons, and predicted that they would act very energetically on the skin or any other tissue with which they came in contact; and that the character of the reaction would resemble that from X-rays and radium, except that it would make its appearance more promptly. This is the substance of the "preliminary note."

II.

If the radiations in question were negative electrons, as are the cathode rays of the Crookes' tube, and the *beta* rays of radium, they would of course be deflected by a strong magnetic field, but efforts in this direction by Dr. Pegram in the Physical Laboratory of Columbia University, by Dr. Milton Franklin at his own laboratory and by myself, failed to give evidence of any deflection.

E. Wiedemann, in the *Zeitschrift für Elektrochemie*, July 20, 1895, described a new form of radiation to which he gave the name of *Entladungsstrahlen*, and stated that it was not deflectible by the magnet and would not pass through flour-spar which readily transmits the ultra-violet rays. He does not appear to have examined the radiations with the electroscope. It is quite possible therefore that Wiedemann's observations related to the "rays" to which I have here called attention.

Excluding ultra-violet rays and negative electrons, it is, of course, possible that they are positive electrons, such as constitute the Goldstein rays, *i.e.*, the anode rays of the Crookes' tube, and the *alpha* rays of radium; neither of which have heretofore been utilizable for therapeutic purposes. There is another hypothesis, however, that seems to me more probable; namely that they are ions.[1] Ions may be generated in a variety of ways and are always developed at the site of an electric spark. Coincidently there is developed an area of high pressure that drives the ions at a high velocity into the surrounding air.

In discussing this question Prof. J. J. Thomson says,[2] that if we have a spark one centimeter long in connection with a condenser of 1,000 cm. capacity the pressure developed will be equal to that of 660 atmospheres (equal to about five tons to the square inch). This pressure, however, diminishes with the distance from the spark according to the law of inverse squares.

When we consider the enormous velocity with which the ions are projected in consequence of the pressure behind them, and the rapidity with which they are developed, it is quite within reason to assume that they will be capable of exerting a considerable influence on tissues that are

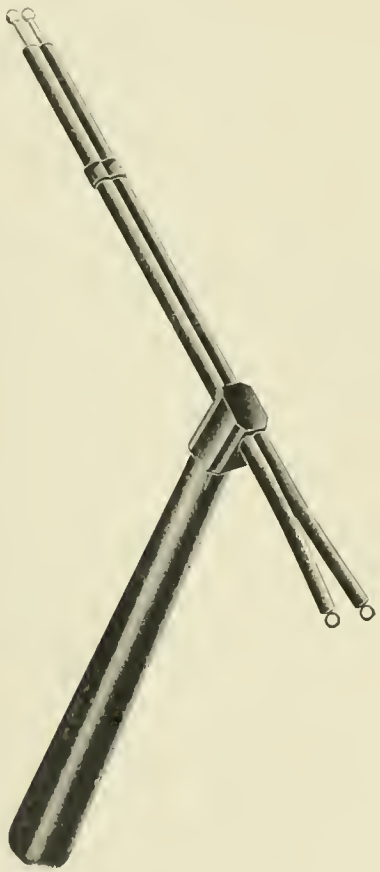
1 The ions of the physicist are not to be confused with the chemical ions resulting from electrolysis.

2 Conduction of Electricity Through Gases, Cambridge (Eng.), 1903, p. 392.

brought within a centimeter or two of their point of origin, and in the earlier writing[1] I suggested that the reaction following the use of the hyperstatic spark might be due in part to the effects of ions on the tissues. Ultra-violet rays also ionize the air, and to this ionization may be due some of the effects observed after their use.

Since my "preliminary" note was published I have found clinically that the "rays" of which I am speaking do exert a very powerful influence on the skin: and that the reaction is similar in character to that of the X-rays and of radium: and that it appears much more promptly. Like them also it may produce a curative or a destructive effect according to the intensity of the spark and the duration of its application.

Fig. 2.



The author's spark-ionizer (about ⅓ scale).

When the spark is produced between iron electrodes with one or more intervening gaps, the total length of the gaps need not exceed one centimeter. If the lamp be used in connection with a coil and suitable condenser, and an application of about five minutes be made with the sparks about 15 mm. from the tissue, a decided reaction will be obtained in soft morbid epithelial and other degenerating lesions. A similar application for fifteen minutes has resulted at my hands in the sloughing out of a lupus nodule. It is important, therefore, that care should be used, especially at the beginning of treatment in any given case. Besides by myself these condenser spark radiations have been used by Dr. Robt. Abbe, Dr. Milton Franklin and Dr. W. H. Dieffenbach, of this city, and by Dr. J. W. King, of Bradford, Pa., with as they have stated to me highly gratifying results.

The use of X-rays in connection with uterine cancer and some epitheliomatus conditions of the buccal cavity present mechanical difficulties that it is sometimes inconvenient to overcome; while ultra-violet rays have not, so far as I am aware, been employed in these conditions. These mechanical difficulties, however, need not stand in the way of those who desire to employ the ultra-violet plus the electrons or ions (or whatever they may be) in these conditions, as the open spark arranged in the form shown in Fig 2, which I have provisionally called a spark-ionizer, can be readily introduced through a speculum or other suitable shield. The particular form of the appliance, as here shown, can, of course, be modified to suit any special requirement.

Fully aware that ultra-violet rays, as well as the ions are superficial in their action, being absorbed by a very thin stratum of tissue, I have, on more than one occasion, been surprised by the evidences of a deeper influence.

The following recent experiment, however, has apparently furnished the explanation: I exposed a piece of velox paper through a glass negative, and obtained a fully-timed print in about one hundreth of the time that would have been required to get one of similar character with a 32 c.p. incandescent light. As neither the ultra-violet rays nor the ions will go through glass, the action on the photo-paper was due wholly to the luminous rays, which, though greatly inferior in *volume* to those from the incandescent filament, very greatly surpassed them in *intensity*. When optically analyzed the entire spectrum from red to violet was exceedingly brilliant.

As the longer wave-lengths of light penetrate the tissues farther than the shorter ones, the cause of the deep reaction of the condenser spark was thus readily explained.[1]

We have thus in the condenser spark three forms or types of energy in coincident action, namely, the intense and penetrating luminous rays; the more superficially acting ultra-violet rays; and the furious bombardment by the ions. To this combined action, the terms triradial or triergic may with propriety be applied.

As regards the technic my experience leads me to recommend: (1) If the appliance be used with a coil, a single Leyden jar should be employed, with inner armature connected with one of the secondary terminals, and the outer armature with the other terminal of the secondary of the coil. The lamp is then connected directly to

1 Radio-Praxis, Medical Record, March 7, 1903.

1 Contrary to the general opinion, I believe that the results of the Finsen treatment are mainly due to the luminous rays rather than to the ultra-violet.

the secondary by its cords. I prefer a Wehnelt interrupter adjusted to give a current of five to six amperes through the primary of the coil. The armatures should not exceed 40 square inches of foil in each. This is for the three spark lamp. For the one spark "ionizer" a lesser amount of energy is preferable. The first application should never exceed ten minutes. (2) If connected with a static machine use two Leyden jars the armatures of which should each have a foil surface of at least 100 square inches. The outer armatures of the jars should be connected together, and the lamp terminals connected to the pole pieces of the static machine. The first application should not exceed fifteen minutes with the spark from 15 to 20 millimeters from the lesion.

256 West Fifty-seventh Street.

EXTRA-UTERINE PREGNANCY: ITS DIAGNOSIS. REPORT OF CASES.

BY ISAAC IVAN LEMANN, M.D.,
OF NEW ORLEANS, LA.

A MERE casual dipping into the contemporaneous literature will serve to convince that ectopic gestations are not of so uncommon occurrence as is the general impression. It is difficult, however, to obtain accurate data as to their frequency and the meager statistical facts occasionally furnished differ widely. Douglas, for instance, quotes Bandl as saying that extra-uterine pregnancy occurred once in every twelve thousand pregnancies, while Price had found it to occur eighty-three times in eight thousand pregnancies. Douglas's own work for fifteen years approximated four cases annually. Williams says that prior to 1876 extra-uterine pregnancy was considered so rare an affection that Henning stated that even the directors of large obstetrical institutions might never encounter a case, and Perry was able to collect only 500 instances from the entire literature. It was only with the gradual development of abdominal surgery that the relative frequency of such pregnancy became recognized. Schrenck, in 1892, collected 610 cases, which had been reported in the preceding five years, and recently many operators have placed on record large series, Kustner having operated upon 105 cases in the course of five years, while Noble encountered extra-uterine pregnancy in three to four per cent. of all his laparotomies. Vineberg reports nine cases that came under his observation in the course of one summer. In a clinic averaging over six hundred gynecological cases a year, it has been my fortune to see three cases of ectopic gestation this past year.

It is doubtful, to say the least, whether it would be possible from the tabulated experiences of one man or set of men to obtain a true idea of the frequency of the condition, owing to failure on the part of the profession in general to recognize it. As Vineberg has well said: "The affection has not met with the same alertness on the part of the profession that appendicitis, for instance, has encountered for some years past." When that same attitude of alertness, of suspicions toward obscure and hitherto little understood menstrual irregularities and pelvic pains, shall prevail, we shall find, as I think we begin already to find, the recorded number of ectopic gestations increasing.

The importance of this attitude of suspicion is emphasized by the history of Vineberg's nine consecutive cases in but two of which was the classical picture of the disease present.

With this idea well fixed in the mind, we may enumerate briefly the symptoms usually held as leading to the diagnosis of ectopic gestation and consider the question of differential diagnosis.

The history of amenorrhea for a month or two accompanied by the usual signs of a normal pregnancy occurring in a woman previously sterile for a number of years; "this amenorrhea being followed by a period of irregular, intermittent bleeding from the genitals, the discharge of a decidual cast from the uterus, and occurrence of occasional severe colicky pains in the lower abdomen, would lead one to the diagnosis of extra-uterine pregnancy; and if upon vaginal examination we should find the uterus slightly enlarged, though not to the size proper to an intra-uterine pregnancy of the period indicated by the history, and further if we should find to one side a fluctuating boggy mass pushing the uterus over to the other side, we should have present all the possible evidence in favor of our diagnosis. When shortly after such an examination we find our patient in a state of collapse, with all the clinical manifestations of internal active hemorrhage, we have been further confirmed in our opinion by the occurrence of intra-peritoneal rupture. But it is precisely these clean-cut unmistakable cases that are of rare occurrence. We must remember in the first place that the symptoms of rupture may be the first to direct our attention to the possibility of the existence of any serious intra-abdominal condition, in fact the woman herself may not previously have been aware of anything amiss. In the presence of such a state of affairs, of course, the question of differential diagnosis is of minor importance, indications for celiotomy being the same no matter what the cause of the intra-peritoneal hemorrhage. In such cases to arrive at a proximate diagnosis we should have to rely in the main upon the previous history. Pelvic examination would yield but little information, the mass, if it had existed, having ruptured and the blood being free in the abdomen.

The history of irregular bleeding following an amenorrhea in a woman presumably pregnant but who had been previously sterile for a number of years leads directly to the consideration of what is probably the most interesting point in the differential diagnosis from early intra-uterine abortion. It will often, in fact usually, be im-

possible to determine from the woman's story the difference between the early abortion and the decidual cast of extra-uterine pregnancy. Both conditions may give rise to a more or less continued or intermittent hemorrhage. In both conditions the uterus may be slightly enlarged. The fact that the patient has been previously sterile or is known to have been the victim of previous pelvic inflammatory trouble, will not lend much weight to the side of tubal pregnancy, as against intra-uterine abortion, nor would the opposite history exclude the extra-uterine gestation. We may be helped by a history of recurrent pains, whether sharp and lancinating, or bearing, boring or dull and throbbing, more especially an account of one or more spells of faintness indicating repeated partial ruptures. But of greatest importance is the vaginal examination. We must not content ourselves with the probable diagnosis of early abortion when presented with a history such as I have tried to outline, but should make careful pelvic examinations, always, of course, with due precautions of cleanliness, and determine for ourselves the true state of affairs. Remember that we may have no pains, no signs of rupture and remember that it is just in this quiescent state that we may hope to be of the greatest assistance. Even upon examination we may find the diagnosis still problematical. If we find a fluctuating mass in the broad ligament to one side we are justified with such a history to make a diagnosis.

Illustrative Case I.—Lizzie Bolden, colored, age twenty-six years. Admitted to the Charity Hospital September 27, 1903. Well nourished. Puberty established at sixteen. Three children. Oldest nine years, youngest one year and a half. One miscarriage five years ago. Has had pain in both groins and back ever since this miscarriage. Previous to two months ago menstruation was perfectly regular, lasting three days at each period. For past two months has been bleeding intermittently for a day or two at a time. Vaginal examination revealed a small fluctuating tumor about an inch and a half in diameter to the right of the uterus. Tumor was freely movable and stood in the same relation to the uterus as the tube would. The right ovary was easily palpated and found normal. Left adnexa normal. Uterus normal in size. Patient gave a history of having passed a decidual cast. Here the history of the patient alone would have led us rather to the diagnosis of very early abortion or of hemorrhagic endometritis. Pelvic examination enables us to localize the trouble in the tube, but left us in doubt as to its precise nature. Salpingitis might very well accord with the history and account for the uterine hemorrhage. However, the tube was freely movable and the ovary was normal in size and mobility—all presumptive evidence against inflammatory trouble. Armed with the suspicion on which I have endeavored to lay stress, I ventured upon a probable diagnosis of extra-uterine tubal gestation. Whether tubal gestation or salpingitis with that amount of fluid accumulation within the tube, the condition called for operative interference. Upon opening the abdomen, October 1, 1903, I found the right tube distended to the size already mentioned, adherent to a coil of intestine not easily separated. After ablation the tube was opened and found to contain a fetus of about six weeks. Patient made an uneventful recovery.

Just here I may remark upon the relative safety of an exploratory laparotomy as contrasted with the very great danger of a curettage in such cases as this. I would not counsel rash invasion of the peritoneum, but exploratory laparotomy should be an operation without mortality. On the other hand, what must have been, in such a case as this, the calamitous consequence of a curettage, that operation so simple and supposedly so devoid of risk, undertaken for the cure of a supposed endometritis, possibly dependent upon the salpingitis? Unavoidable rupture of the pregnant tube, internal hemorrhage and death of the woman.

From normal pregnancy there should be no differentiating the abnormal gestation. The soft fluctuating body of the uterus plainly continuous with the cervix can hardly be confused with the tube. Small ovarian cysts with torsion of the pedicle may simulate ectopic gestation in symptoms both subjective and objective. Douglas points out that the points of difference here would be: (1) Signs of pregnancy; (2) amenorrhea; (3) passing of decidual membrane in the history of an ectopic; (4) upon an examination we should find the uterus drawn over to the same side by the taut pedicle of the cyst, whereas that organ would be displaced invariably to the opposite side by the pregnant tube.

But not only in the early (unruptured) stage is the diagnosis of ectopic gestation difficult. Even when the pregnancy has continued to term and the patient has withstood the, it may be, repeated ruptures of the gestation sac with limited hemorrhage and the dangers of missed labor, and even come into the depths of sepsis, the diagnosis is obscure and perhaps impossible. I may best indicate this to you by the relation of

Case II.—Ollie Wilson, colored, aged twenty-nine years. Admitted to Charity Hospital April 14, 1903. Personal history: Began to menstruate at thirteen years. Regular periods four to five days, slightly painful. One child, three years ago. No miscarriages. Present illness began eleven months before admission. Pains in hypogastrium, violent, attended with vomiting and prostration severe enough to cause patient to go to bed for some time. Since that time has noticed gradual development of tumor in hypogastrium. Has had severe attack of vomiting and severe abdominal pains. Menstruates regularly, but periods last from seven to nine days. No history of menstrual cessation prior to above symptoms. Occasional chills followed by fever. Fever often without chills preceding it.

Status præsens.—Septic appearance marked; septic temperature. Tumor soft and fluctuating, filling hypogastric zone and rising midway between umbilicus and ensiform cartilage. Extremely painful and tender. Chill twenty-four hours after admission. Vomits persistently since that time. Pulse hard and rapid, without sustained volume. Vaginal examination shows tumor apparently connected directly to uterus. Difficult to define accurately limits of tumor owing to pain. Cervix hard; os small. Adnexa not palpable. Condition is one of a suppurating encysted collection. History is suggestive of extra-uterine pregnancy. Probable diagnosis prior to operation: Suppurating ovarian or dermoid cyst.

Operation.—Upon opening the abdomen, a large fluctuating mass, adherent to intestines and in part to abdominal parietes above, presented itself through the incision. Aspiration showed this to contain a slightly greenish-yellow non-purulent watery fluid. The cyst was incised and contents allowed egress. Posteriorly and a little to the left of this was another cyst, aspiration of which revealed the presence of a greenish, serous and slightly blood-streaked pus. Attempts to free the cyst from surrounding adhesions resulted in its rupture. It was found on exploration of its cavity, to contain fetus, apparently full-term, showing conditions of beginning maceration. Placenta well formed. Fetus removed after ligation of cord. An acute exudative peritonitis was present involving the entire peritoneal surface, both parietal and visceral, from pelvis to diaphragm. Exudate was removed with sponges and the abdomen and pelvis flushed with normal saline solution. No attempt was made to remove the placenta. Gauze drains were passed up to the diaphragm and down into the pelvis to those points indicating the severest local peritoneal infection, the end of these drains being brought out through the abdominal wound. This was sutured to the abdominal wall and the sac cavity was filled with iodoform gauze. The abdominal wound was partially closed with interrupted through-and-through silkworm sutures. Death eight hours after operation from post-operative shock and effects of toxemia prior to operation. No post mortem. This patient was profoundly septic upon admission and her very grave condition demanding immediate operative interference was plainly due to some collection of pus within the cyst. What the nature of that cyst originally was could not be made clear without the operation urgently demanded for the relief of the condition. But while confessing one's inability to make this positive diagnosis at this stage, must not our thoughts necessarily come back to the question: Could not the diagnosis have been made earlier, before the woman had became septic and when the chances for recovery would have been enormously increased? Was not the history of repeated pains and prostration with the progressive growth of a fluctuating tumor sufficient reason months before to arouse the suspicion of the attending physician and to cause him even in the absence of a positive diagnosis to insist upon an exploratory operation and an inspection of the pelvic condition Did not the history at least call for a careful bimanual examination early in the disease and would not this have revealed the presence of what was then a small fluctuating tumor. This latter would have demanded surgical procedure.

I end as I began. I believe:

1. This disease is a far more frequent one than most of us now believe it to be.

2. By maintaining an attitude of alertness and by carefully investigating all conditions of menstrual irregularities and colicky pains, we shall find ourselves warranted in establishing an accurate diagnosis and saving the lives of some patients who would otherwise perish.

3. That when the diagnosis is obscure in the presence of a boggy or fluctuating mass to either side of the uterus, we are justified in doing an exploratory operation either through the abdomen or the vaginal fornix.

PANCREATITIS.

BY W. D. HAGGARD, M.D.,
OF NASHVILLE, TENN.;
PROFESSOR OF GYNECOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF TENNESSEE; FORMERLY PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY, UNIVERSITY OF THE SOUTH; GYNECOLOGIST TO THE NASHVILLE HOSPITAL.

The pancreas, the most sequestered organ in the abdomen, has at last yielded up in part the secrets of its obscure and incorrigible inflammations. The frequency with which it is associated and indubitably caused by gall-stones makes it a more easily comprehensible and less forbidding disease to the surgeon. The violence of onset and the gravity of the symptoms render it of great importance to the diagnostician. The intricacy of its physiology and the uniqueness of its varied tissue changes open an inviting field to the pathologist, while the unraveling of its complex phenomena and etiology make it at this time of peculiar interest to the pure scientist.

Inflammations of the pancreas were formerly supposed to be very rare, but the result of recent investigations and the accumulated work of clinicians have shown it to be much more frequent than it was supposed to be, and, moreover, certain curable forms may remain undiagnosed and leave no trace behind.

Acute Pancreatitis.—Fitz, in his original classical description, divided pancreatitis into hemorrhagic, gangrenous, and suppurative. This is a most accurate pathological division, and in some cases the variety can be designated, but usually they shade into each other, and thus appear as progressive stages of the same process with a common cause. The clinical classification of Robson, therefore, into acute, subacute and chronic would seem to be the most desirable.

It can occur, therefore, with or without hemorrhage, suppuration, gangrene, or fat necrosis.

Etiology.—The causation of this disease, ever since it has been recognized with any degree of frequency, has been shrouded in mystery. Many theories were offered, and the explanations required further explanation. Like most things, when the true explanation is found, it turns out to be very simple. Mr. Mayo Robson, in connection with his gall-stone work, observed cases of induration of the head of the pancreas with gallstones in the common duct. It had been noticed by pathologists that at necropsy pus can usually be expressed from the duct of Wirsung in these cases.

Robson has drawn our attention to the obvious fact that a stone obstructing the common duct at the ampulla of Vater must necessarily obstruct the duct of Wirsung, and also that inflammation of the bile duct as the result of cholelithiasis is perhaps the most prominent etiological factor in the chronic, indurative, interstitial, or cirrhotic form.

Kennan, in 1896, Körte and Lancereaux, in 1898, and Oser observed this coincidence; but Robson, who saw his first case in 1892, seemed to be the first to grasp the comprehensiveness of the occurrence and to bring it succinctly and forcibly to the attention of the profession in 1900.

The anatomy and mechanism of this process may be briefly quoted from Opie as follows:

"The orifice of the diverticulum of Vater constitutes the narrowest part of the bile channel, and here small calculi not infrequently become impacted. A small stone lodged in the diverticulum may occlude its duodenal orifice, and, too small to completely fill the diverticulum and occlude the two ducts that enter it, may convert the latter into a single closed channel along which bile may be forced by the gall-bladder. Bile thus injected into the pancreatic duct causes, as will be subsequently shown, the condition known as acute hemorrhagic pancreatitis. This lesion does not commonly follow the expulsion of a gall-stone from the common duct. For its production it is necessary that the diverticulum of Vater be capacious, with a length at least greater than the diameter of its duodenal orifice."

As bearing upon the possibilities of the entrance of bile into the pancreas it may be mentioned that in dogs death has been caused in twenty-four hours by the injection of 5 c.c. of bile into the pancreatic duct.

Opie, supported by Welch's investigations, claims that the bacteriological findings have been so variable and inconstant that they do not enter into the etiological factorage, but are merely secondary invaders of injured tissue. He has placed the relationship between gall-stone in the ampulla of Vater and acute pancreatitis upon the same fortified position as Robson did between the common duct stone and chronic pancreatitis. He had the previous observations of others and his own careful study of the post mortem on Osler's case, operated by Bloodgood, of acute hemorrhagic pancreatitis followed by death, and finding a small stone at the duodenal papilla.

To this carefully worked-out case he has added the reports of seven others in which the stone was actually acting as a ball, occluding the exit of both ducts into the duodenum and allowing the bile to flow directly into the pancreatic duct. He properly infers that in many cases the stone may be temporarily lodged long enough to cause damage to the pancreas, and then escape, leaving no actual evidence of its former impaction. He also tabulates forty-one cases of acute pancreatitis with cholelithiasis, certainly enough to establish an undoubted causal relationship and food enough for further theorizing as to the rôle of infection associated with gallstones and productive of pancreatitis.

Robson and Moynihan contend in their monograph that the immediate and essential cause of pancreatitis is bacterial invasion, but mentions as exciting causes biliary and pancreatic calculi, trauma, gastro-duodenitis, gastric and duodenal ulcer, and carcinoma, and certain infectious diseases, such as typhoid fever, influenza, and mumps. In some cases occurring suddenly in perfectly healthy persons the exact cause cannot be designated.

Fat Necrosis.—Aside from the usual pathological changes which take place in gangrenous and suppurative inflammations, the distinctive tissue change in this disease is fat necrosis. This occurs when, as the result of obstruction of the excretory duct, the fat-splitting ferment of the pancreatic juice penetrates into the tissues about the organ.

The obstruction is gradual in chronic pancreatitis, and the penetration of the pancreatic juice is so slow that minute foci occur. In acute hemorrhagic pancreatitis or its later stages, gangrenous pancreatitis, the fat necrosis is more widely disseminated. The retrojection of bile into the pancreatic duct, causing necrosis of the parenchyma of the gland, dams back the pancreatic juice that is present, thus causing fat necrosis of the fatty tissue surrounding the pancreas. The fat is split into its component fatty acids and glycerin. The latter is absorbed, and the former unites with the lime salt to form yellowish-white, non-elevated, opaque spots about the size of a millet seed. They resemble miliary tubercles or carcinomatous nodules, but occurring sometimes in the subcutaneous fat and regularly in the subperitoneal fat as well as the omentum, one should be able to recognize them by this means as well as by their brittle feeling, and recognize that they point almost as unerringly to disease of the pancreas as jaundice does to disease of the liver.

Symptoms.—Acute pancreatitis is characterized by sudden onset of severe agonizing pain in the upper abdomen, producing syncope or collapse, recurring in paroxysms and aggravated by attempted motion. The pain is described as most excruciating, almost invariably requiring

morphine for its relief. Immediately following the pain, tenderness, well-marked between umbilicus and ensiform appendix, makes its appearance.

Distention of the upper abdominal zone succeeds the pains, becoming general late in the disease. Cyanosis of face and abdomen has been noted in a number of cases, and in one was the most suggestive symptom.

Usually vomiting is an initial and most annoying symptom, first of food and then of bile, and sometimes blood. Though it is not always present it may be very severe, and increases the pain, thus adding greatly to the distress of the patient.

Slight jaundice from coexisting catarrh of the bile tract may be present. Facies present a pinched and anxious expression, and may be Hippocratic in its depiction of suffering and impending death.

The pancreas is generally enlarged, but the great pain, exquisite sensitiveness, and marked distention preclude an accurate palpation of the organ in its deep-seated position.

Glycosuria is rare, because, as demonstrated by Opie, the disease primarily attacks the excretory apparatus and does not affect the islands of Langerhans, which preside over the glycosuric function. In only two of forty-one cases of hemorrhagic pancreatitis, and in only three out of forty cases of gangrenous pancreatitis collected by Körte, was sugar present.

Effort has been made to recognize clinically the fat-splitting ferment in the urine by chemical test. Ethyl butyrate, carefully purified when acted upon by a fat-splitting ferment, is decomposed with the formation of butyric acid, which gives an acid reaction to the solution.

Ascites may result from pressure on the portal vein, from an induration or abscess in the head of the gland, as in a case reported by Musser. Most victims of this disease are markedly fat. The pulse is rapid and thready. Temperature is variable and not an accurate index of the severity of the condition. Hiccough sometimes occurs, and is very distressing and sometimes uncontrollable. Delirium may appear in the later stages and be quite unmanageable. Death from collapse often occurs in from two to five days, though the patient may survive longer in less acute case, and recovery sometimes follows.

Diagnosis.—Symptoms of peritonitis in the upper abdomen are suggestive of pancreatitis. Intestinal obstruction is very closely simulated. Several of the reported cases were operated on with that diagnosis, and the real condition was ascertained only after obstruction was fruitlessly searched for. Fitz's rule, quoted by Robson, is as follows:

"Acute pancreatitis is to be suspected when a previously healthy person or sufferer from occasional attacks of indigestion is suddenly seized with the violent pain in the epigastrium, followed by vomiting and collapse, and in the course of twenty-four hours by a circumscribed epigastric swelling, tympanitic or resistant, with slight rise of temperature."

When confronted with a case presenting the foregoing syndroma, one has to discriminate intestinal obstruction, biliary colic, cholecystitis, intestinal perforation, and gangrenous appendicitis.

In intestinal obstruction the distention will usually be greater and more general; in pancreatitis it is frequently limited to the epigastrium. In intestinal obstruction the peristaltic patterns can often be seen, and the waves may be heard by auscultation. The obstipation is absolute, whereas in pancreatitis the bowels may move, or at least gas is often expelled. In intestinal obstruction the vomiting finally becomes stercoraceous. Collapse is early in pancreatitis and late in intestinal obstruction. Temperature is commonly present in the beginning of pancreatitis. Its presence in the initiatory stage eliminates intestinal obstruction. The pain is lower down in intestinal obstruction and comes on more in paroxysms. Intestinal obstruction may complicate pancreatitis by strangulation or compression of the duodenum. The final diagnostic and curative measure in both is abdominal section. Fat necrosis is pathognomonic of pancreatitis when present.

Pain in pancreatitis is similar to a severe attack of biliary colic, but more intense. In biliary colic it is situated to the right of the median line and extends upward under the right shoulder. In pancreatitis it is situated in the median line and extends to the left.

In phlegmonous cholecystitis, or rupture of the gall-bladder or ducts, the acute symptoms are often preceded by tumefaction or tenderness at the tip of the ninth costal cartilage. After peritonitis ensues from any cause the symptoms of the original disease are lost in the all-too-well-known and fatal complication.

Intestinal perforation (stomach or duodenum) will present a preceding history of the more or less classical story of these affections, and the escape of gas and the advent of peritonitis after the perforation is generally attended with an absence of liver dulness. Moreover, the vomiting which is so persistent in pancreatitis, usually subsides in perforation of the upper alimentary canal, until consecutive peritonitis is declared by its return.

In perforative appendicitis, while the initial pain may be about the umbilicus, the localization of pain, tenderness, rigidity, and perhaps swelling in the right iliac fossa, render differentiation easier than perforative lesions in the upper abdominal quadrant.

Treatment.—While the futility of medicinal treatment is recognized the excessive pain requires relief, the collapse demands stimulation, and the vomiting can be ameliorated by gastric lavage.

Surgical intervention is precluded in the stage of collapse. The disease, from the indefiniteness of the symptoms, is either not suspected or the

symptoms of obstruction or perforation seem to be dominant. Should operation be undertaken upon this ground, or even upon a correct diagnosis, as urged by Mikulicz, fat necrosis will at once clinch the diagnosis. The organ may be reached through the gastrohepatic or gastrocolic omentum, or by the posterior approach at the costovertebral angle.

Mikulicz definitely advises incision of the tense-walled sac, that often feels, as described by Mayo in his successful case, "like a pudding in a tight sac." An incision four inches long and three-quarters of an inch deep in the pancreas was made by Porter, followed by drainage and recovery. A large gauze drain surrounded with guttapercha tissue is the best anterior drainage. In the gangrenous or suppurative form posterior drainage through incision in the left costovertebral angle is advised.

Roswell Park likens prompt operation in this condition to early interference in fulminating appendicitis. Mikulicz compares severe cases of acute hemorrhagic pancreatitis to an acute phlegmon in which, on account of its peculiar consistency and secretion, an unusually severe course is run. He urges incision and drainage of toxic contents, thereby escaping sepsis and further destruction of the gland.

Subacute Pancreatitis.—It is well known that some cases, while presenting a sudden onset, run a less virulent course and survive a longer time. Some have been submitted to operation, and after the diagnosis was made intra-abdominally, very little or nothing was done, ending in recovery.

Robson reserves this classification of subacute pancreatitis for such cases, without marked collapse, less severe and protracted vomiting, and without such rapid and well-marked epigastric swelling. The tenderness is much less, and distention being not so great, the enlarged pancreas may be palpated, especially under an anesthetic.

Blood or pus may appear in the fetid diarrhea consecutive to the initial constipation. A septic temperature with rigors often occurs, and then abetes, with apparent general improvement until a recurrence of acute symptoms takes place, with great weakness and loss of weight, and finally death occurs. These cases sometimes terminate in suppuration of the pancreas of pancreatic abscess, which may burrow, according to Robson (1) behind the stomach; (2) into either loin; (3) under diaphragm (subphrenic abscess); (4) along the psoas muscle (subperitoneal iliac abscess); (5) under peritoneum into left broad ligament.

Chiari reports two cases where the portion of a necrotic pancreas was passed per anum with recovery. This termination, even in pus cases, is, however, not always so favorable, and death usually takes place from prolonged sepsis of imperfect drainage.

This type of the disease being comparatively mild does not appear to demand surgical intervention or other heroic treatment so urgently as the acute form, and, suppuration occurring, the surgical indications become clear, and incision may be made over the pus collection for drainage. After a complete examination of the relations of the abscess cavity, if found to be still retroperitoneal, posterior incision at the right or left costovertebral angle may be made, as suggested by Robson. The whole hand may be introduced, pus collections broken up, and efficient drainage instituted without danger of peritoneal contamination. Robson and Moynihan reported three successes out of five cases of suppurative pancreatitis.

Chronic (Interstitial) Pancreatitis.—This is divided about equally between the sexes. Two-thirds of the cases occur between forty and sixty. It is usually the result of obstruction of (*a*) pancreatic calculi in the duct of Wirsung; (*b*) gall-stones in the common duct or ampulla of Vater; (*c*) neoplasms, usually malignant, obstructing the outflow of the pancreatic fluid.

The pancreas is easily obstructed, because the accessory duct joins the main duct within the gland in 90 per cent., or if, as occasionally, it enters the duodenum independently, the orifice is usually so small that it is unable to allow of free exit if the main duct is occluded.

Duct obstruction constitutes a propitious condition for the invasion of bacteria, which is believed by some to be the essential cause, and the access of the bile, if it does not give rise to rapid necrosis, causes a chronic hyperplastic inflammation.

In three cases of chronic (interstitial) pancreatitis detected by the stony indurated feel of the pancreas during operation for gall-stones, Riedel feared malignancy; but two of the cases recovered and remained well for a number of years, thus disproving the idea of malignancy, and the diagnosis in the third was confirmed after death. Doubtless many cases have been denied operative relief, even when the surgeon was in the abdomen, upon the supposition of the indurated head of the pancreas being distinctly malignant.

Extension of infection from inflammation of the duodenum and bile tracts may be operative in its production. Moynihan reports a case of operation where chronic pancreatitis of stony hardness was found, due to infection with typhoid bacilli nearly two years after the fever. The gall-bladder was drained, the bacilli were found in the discharge for weeks, and then ceased. The boy recovered.

Chronic interstitial pancreatitis may also occur from general or local tuberculosis. It results from excessive use of alcohol, just as cirrhosis of the liver does, and is said to be associated with the latter in one-quarter of the cases.

The chronic changes as the result of interstitial effusion gradually enlarge the pancreas, which presses against the common duct, giving the usual jaundice

Symptoms.—In patients with stomach pain, chronic jaundice, and emaciation, give the patient the benefit of the doubt, and consider chronic pancreatitis as well as cancer and gall-stones. The patient is often a dyspeptic or gall-stone sufferer. Exacerbations of epigastric pain occur, and may be replaced by a deep-seated ache. Nausea and vomiting alternate with anorexia, belching, etc. Finally, jaundice makes its appearance with attendant putty stools. Emaciation follows, and the cachexia of malignancy is simulated. Marasmus closes the scene.

In the diagnosis midepigastric tenderness serves to distinguish pancreatitis from cholangitis and cholecystitis. Undigested fibers of meat may appear in the stools. Lipura and glycosuria are late symptoms.

It is not so important to discriminate between gall-stones and chronic pancreatitis, as the treatment of both is the same. In cancer of the pancreas the secondary anemia and leucocytoses may distinguish it, and the cachexia and painless distention of the gall-bladder is corroborative. Exploratory section is justifiable in doubtful cases.

In obstruction to the outflow of pancreatic juice undigested meat fibers may be found in the feces after a meat diet. Salol, when administered in large doses, should be split into its components—carbolic acid and salicin—by the pancreatic juice, and their absence in the urine is an accurate test.

The Mayos have reported operations upon seven cases, all recovering; four were treated by cholecystostomy, and three by cholecystenterostomy, twice to the transverse colon and once to the duodenum, the results being as good where the colon was used as the duodenum.

In the treatment, appropriate operations on the bile tracts to free them from obstruction, followed by drainage, is the indication. The results have been quite satisfactory. Robson lost only one case out of twenty-two operations, and Mikulicz collected thirty-six cases with five deaths.

LAUNDRY HYGIENE.

BY IRA S. WILE, M.D.,

OF NEW YORK.

"Cleanliness is near akin to godliness." Wesley's dictum daily grows in grandeur and strength. Cleanliness is now one of the main supports of organized communities and a most prominent factor in preserving them from disease and decay.

From organizations of men for self-betterment, for mutual protection and development, have arisen our great systems of manufactories. From cooperation and division of labor have come the trades and professions. Regard for the general health has directed the management of industries along lines of safety so that no portion of a community need suffer unnecessarily because of industrial progress. There has been evolved a higher industrial morale and more rigid sanitation, based upon the most searching examination of the effect of each industry upon the community as a whole and upon the workers as a class. Exposure to undue congestion, to filth, to disease, has been gradually lessened. The factory laws and tenement inspections evince the lively interest taken by the State in preserving the health of the great mass of workers. Cleanliness has become an index of industrial hygiene. The state of civilization may indeed be gauged by the soap-bill of a nation.

To keep pace with the gross advancement individuals have had to give especial attention to the problems of personal hygiene. To meet the complicated conditions arising from the division of labor, it has been necessary to support a class with the principal duty of providing facilities for the proper cleansing of articles of attire and household use. The laundry system has grown up to relieve the needs of the cleanly and satisfy the demand for hygienic apparel, etc.

Disregarding the general form of organization, it is not unfair to ask if laundries in themselves are hygienic. All sorts of clothing, bedding, towels, etc., are collected from all sorts of people with all sorts of diseases. This mass of soiled, often polluted and infected, material is collected, assorted, marked, carried hither and thither by employees before being subjected to the heat and chemical process incident to thorough laundering. During the manipulation preceding sterilization, the soiled articles are sources of danger to the health of the various employees handling them. In the processes of drying, ironing, reassorting, checking and wrapping, the employees become possible sources of infection to the owners of the various articles passing through their hands. While this is equally true for machine and hand laundries, in the latter the dangers to either employee or patron are increased because of increased handling. As an offset, however, is the lessened amount of infected material handled at hand laundries. Bearing these two aspects in mind it seemed not unnatural to enquire as to the precautions taken by laundries to protect their employees from infection and prevent the transmission of any disease from employee to patron. To get a little light on the question a personal letter was sent to every laundry in the city of Rochester, N. Y., briefly stating the information desired by the writer and asking for answers to five questions enclosed on a separate sheet of paper. Names were not to be signed to the replies. No evidence of good faith was requested beyond the courtesy of a response. The questions submitted were as follows:

1. What precautions, if any, do you use to prevent infection of employees in handling soiled materials from time of collection to delivery?

2. Do you have much illness among employees? If so, of what character?

3. Do you know of any specific diseases which have been spread? If so, what ones?

4. What means do you have of protection of patrons from diseases of employees?

5. Is tuberculosis common among employees? Among diseases to be considered I should like to suggest as examples, typhoid, scarlet fever, smallpox, syphilis, diphtheria, gonorrhea, infected fingers, inflamed eyes, etc.

The answers vary in methods of expression, but are practically uniform as to statement of existing conditions in the trade.

1. No especial precautions are taken to prevent infection of employees. Particularly filthy materials are not accepted, or, if accidentally received, are not laundered. Articles of wearing apparel, towels, sheets, pillow cases, are not received from places where contagious diseases are known to exist. "We *never* call at a home where they have a sign put up by the Board of Health." The marking room is kept as clean as possible and thoroughly scrubbed at least once a week.

2. The variations in answers were from plain "No" to the interesting statement "Girls become stronger and gain weight in the laundry." As far as could be learned illness is no more frequent than in any other business establishment, employing large numbers of workers. The ailments are merely of ordinary types and in no way dependent upon the vocation.

3. No specific cases of contagion have been found due to or even attributed to handling infected garments, underwear, sheets, towels, etc. Among the employees, there does not appear to be any particular susceptibility to the various infective micro-organisms. One laundryman was expressly explicit: "We have not had one case of contagious disease in our place since January 3, 1880, when I first entered the laundry and we handle tons of goods every week." This statement is probably a little more enthusiastic than accurate. It does emphasize, however, the comparitive freedom from contagion of those handling the soiled clothes of a city.

4. From the answers as to means of protecting patrons, several are worthy of attention. As a matter of fact, no systematic, intentional protection to patrons is deemed necessary. Exposure to heat and chemicals along with mechanical agitation destroys the hardiest of bacteria. During the transition from soiled to clean clothes contagion is abolished.

From the diseases of employees no more sufficient protection to patrons can be desired than that gained during the laundering process. That steam, lime, potassium permanganate, oxalic acid, sulphurous acid and numerous other chemicals employed afford almost complete sterilization cannot be denied. Some concerns stated that they refuse to employ girls appearing or known to be unhealthy. It is not strange that one indignant soul should write: "We have yet to hear of the first instance where disease was transmitted from employees to customers." That is more readily believed than the value of another man's admission that he used hygienic soap to wash the clothes. Oh, Hygiea! how many crimes are committed in thy name!

5. Tuberculosis is no more common among laundry employees than among the workers in any modern, regularly inspected, hygienic, light, airy factory. The moist atmosphere, the frequent scrubbings and lessened dust, tend to keep the omnipresent *Bacillus tuberculosis* in marked subjection. The suggestion of one scientist was thankfully received: "Starching is the best employment for consumptives." Possibly laundries thus possess in starching a beneficent prophylactic measure.

This résumé of the answers to my queries may be of interest to others. It is undeniable that with all the disease germs, known and unknown, which are daily taken to the laundries, little is heard of disease being spread through their medium. My answers are based merely upon established public laundries and not upon an investigation of laundresses who "take in washing" or yield their services at the homes of their patrons.

How do the statements quoted correspond with the facts as observed and recorded by medical workers?

In 1877 the *Lancet* appointed a commission to investigate the laundry system of the time with a view to ascertaining the dangers of disseminating disease through the system then in vogue. A few instances were found where disease had been spread among the families of laundresses and those of their patrons. Because soiled linen was taken to the homes of the laundresses, the danger therefrom was pronounced imminent. Following the report of the *Lancet* Commission, large public laundries were instituted to secure hygienic handling of soiled linen.

From the health laws of England we learn that the hours of labor are restricted to sixty hours per week for women and thirty hours per week for children; the temperature of the ironing rooms must be regulated; ventilation and carrying off of steam from the wash house is obligatory; clean floors and general cleanliness is demanded. This is the present extent of the English laws protecting the health of laundry workers.

In 1896, in the Council of Paris, discussion arose concerning the risk of the spread of infectious fevers through laundries. A commission, with Dechamps at the head, was appointed to investigate the subject. It was recognized that public laundries and municipal disinfecting plants could handle satisfactorily the soiled linens from contagious cases providing notification of the Health Bureau was demanded. The community was unprotected, however, when the contagious disease was unrecognized or belonged to the category of unreportable disease. It was not necessary, nor is it to-day, to report venereal diseases, purulent local infections, dysenteries, tuberculosis, etc. Linen from cases of this nature was

regarded as a source of public danger. The intelligent report advised sealed sacks for transportation of soiled linen to laundries and disinfection before sorting and especial attention to pus or blood-stained articles.

Abbot, discussing the dangers from hospital laundries, urges immediate, moist disinfection of dirty linen. He mentions the danger of spreading disease through dust from dry sputum, blood, pus, feces, etc.

Viola and Morello have shown the high bacterial content of soiled linen and their resistance to weak disinfectants. From their work it is apparent that disinfection should be obligatory before many persons are permitted to handle the disease-laden materials.

In "Risks and Dangers of Various Occupations," Parry does not include laundry work as one subjecting the worker to any particular liability to disease. Dammer refers to the frequency of bronchitis and the diseases of women among laundresses. Arlidge carefully analyzes the work of laundries and attributes the main ailments of laundry workers to the character of their work. He mentions "exposure to steam, long immersion of hands and forearms in very hot alkaline and soapy water, prolonged standing and considerable labor falling on trunk and upper extremities." Little is said of the danger of infection from handling the soiled infected linen. The merest suggestion exists in his reference to the frequency of "erysipelas, onychia and festering sores." Bronchitis is prevalent because of the inhalation of steam, the sudden changes of temperature incident to going to and from the hot steaming washroom and the cooler drying room. No especial stress is laid upon the possibilities of tuberculosis infection from sorting dry, bacilli-laden handkerchiefs, towels, sheets, etc. He quotes an unnamed writer (1891) who gave, as the results of his investigations at Brompton Consumption Hospital, the report that for two and one-half years, two and one-half per cent. of the patients admitted were laundresses.

Dechamps reported that tuberculosis was uncommon among washerwomen. In 1902, the report of the Metropolitan Hospital of New York City did not show a laundress in its statistics of occupations of tuberculosis patients. In a symposium on the "Relations of Phthisis to Factory and Workshop Conditions" (*British Medical Journal*, 1902), due consideration was given to the pervalence of tuberculosis among laundresses. English institutions are discussed and the predisposing causes, mentioned as existent in England are not applicable to this country. Commonness of intemperance and "beer lunches" among laundry workers is not true in America. Much force is given Brouardel's statement that alcoholism predisposes to tuberculosis. The danger to sorters from dried tuberculous material is, however, properly recognized.

In the statistics of Wandsworth and Clapham Union Infirmary, drawing its patients largely from laundresses, Miss Deane reports that, during 1899 and 1900, 8.7 per cent. of laundresses admitted had tuberculosis as against 5.3 per cent. among all others admitted. For seven and one-half years preceding 1900, 9.68 per cent. of laundresses had tuberculosis while only 5.69 per cent. among others actively employed and 7.02 per cent of the unemployed patients were tuberculous. Isleworth Infirmary gave 10.9 per cent. for tuberculosis among laundresses and 4.5 per cent. for non-laundresses.

To get a few medical figures I have taken the reports of St. Francis Hospital, 1903; Presbyterian Hospital, 1903; Mount Sinai Hospital, 1903; German Hospital, 1899; Methodist Episcopal Hospital, Phila., 1899.

The accompanying table shows the total number of cases and the percentage of laundry workers to the total number. For comparison, a few other vocations receive slight notice.

	1	2	3	4	5	Total.
Total cases.	2,301	2,912	3,322	769	3,091	12,395
Percentage, Laundry workers.	1.0	1.5	0.15	0.3	0.35	0.69
Laundresses	19	40	3	1	11	....
Laundrymen.	4	5	2	1	....	....
Clergymen.	17	7	....	15	....	....
Factory girls.	13	17	....	...	....	....
Clerks	55	93	76	16	85	....
Dressm'k'rs.	...	35	....	...	....	....

Barbers.	...	....	....	...	15	....
Salesmen.	...	....	....	...	27	....
Salesw m'n.	...	....	....	...	2	....

I regard these and similar statistics as of very little value, wherefore their fewness. They afford no basis for medical reasoning. As a source of information regarding relation of occupation to health they are useless. They fail to differentiate medical from surgical cases. They do not show if a patient's presence in hospital was due to disease or injury contracted during period of employment or idleness. The effect of occupation is lost in cases of married women who are for the most part registered as housewives. It is apparent that a laundress may marry and die, for example, of a tuberculosis whose origin dated to the days she sorted linen. The term laundress is too general to give reliable information. It covers the "day-out washerwoman," the worker in a hand laundry, the attendant at a large machine laundry. It fails to include the very numerous handlers, sorters, wrappers, who may give their occupations as clerks or even factory girls. The drivers who first handle the soiled linen are wholly ignored. Aldridge rightly noted the difference in the influence of environment. On the one hand, there is the laundress who works at the house of the wealthy, the poor woman who takes her wash home and, on the other hand, the

girl who goes to work in a laundry. The conditions under which the same general work is done vary vastly in hygienic import.

The source of the statistics must also be considered. One hospital draws more largely from one sort of types, class, race, workers, than another. For example, 3 had no clergymen while 1 had 17: 3 had five laundry workers and 2 had 45.

The Isleworth Infirmary was chosen for figures on tuberculosis because laundresses were particularly frequent as patients. If we could get the sum total of all hospitals, with a finely analyzed system of occupational statistics, figures might be more valuable. The number of patients in any one or number of hospitals should be compared also with the estimated number of workers, in that particular trade or profession, living in the community from which the hospital draws its patients. This is open to objection, however, because the mere number of patients of a class in hospitals presents little information regarding health of the occupation. For instance, a fire might send 25 laundresses to various hospitals. The increase of laundresses in the occupation statistics might give unmeant testimony to a health statistician unacquainted with the catastrophe swelling the per cent. list without leaving a trace of the real cause.

These various criticisms of my quoted figures demonstrate the hopelessness of ascertaining from medical sources the dangers to laundresses from handling soiled linen. Until some other facts and figures are available, it appears necessary to coincide with the opinions expressed by the laundrymen themselves.

Laundering appears to be an efficient hygienic method of promoting cleanliness without marked danger to patron and with comparative safety for the employee.

Dr. Frazier Elected to Episcopal Hospital.—Dr. Charles H. Frazier, Dean of the Medical Department of the University of Pennsylvania, has been elected to the surgical staff of the Episcopal Hospital. He takes the place made vacant by the resignation of Dr. R. H. Harte. The votes for Dr. Frazier and Dr. James P. Hutchinson were so close there is talk of increasing the staff from four to five and appointing Dr. Hutchinson to the extra position.

SOME REMARKS ON DIPHTHERIA BACILLI.

BY E. ANDRADE, M.D.,
OF JACKSONVILLE, FLA.;
BACTERIOLOGIST STATE BOARD OF HEALTH OF FLORIDA.

Diphtheria bacilli have been classified according to their size into long, short, and medium bacilli. As a general rule, the long variety is the most virulent. The majority of later observers have classified them according to the manner in which they stain with Löffler's blue, into granular, barred and solid forms; the granular forms being the most characteristic.

Drs. Westbrook, Wilson and McDaniel, of the Laboratory of the State Board of Health of Minnesota, made an extended and painstaking study of these varieties as observed in their State, and subdivided them into types according to their size and other minor differences. Before giving the details of these types, I desire to state that though in cultures from throat exudates some solid forms of diphtheria bacilli may be found, these, by themselves, do not authorize the diagnosis of diphtheria, however characteristic their arrangement may be.

The granular forms are of seven types, and the presence of bacilli of any of these types is by itself characteristic of diphtheria. The second group or barred forms present six types, and likewise the solid forms.

The granular forms show spherical or ovoid granules. In all the types, excepting type B, the granules are methachromatic, taking a reddish tint with fresh Löffler's blue. The granules are usually at one or both poles or may occur elsewhere.

The bacilli belonging to the second group show a distinctly barred appearance as of an actual severance of pieces of protoplasm. The darkly staining portions vary in the intensity of coloration, but do not show methachromatism.

The smaller types of this group, types D and E, are not characteristic, and look very much like the *Bacillus xerosis*.

The solid forms include solidly staining forms of all shapes and also some having the appearance of diplobacilli.

This diplobacillary form includes those which many call pseudodiphtheria bacilli. The bacilli of this group, when found alone, will not suffice to make a diagnosis of diphtheria.

During the past year of laboratory work I have carefully noted the different types found in swab and culture examinations with the object of ascertaining whether here in Florida the same types are found as in Minnesota.

The outfits furnished by the laboratory for the collection of samples of suspected diphtheria, do not contain any blood-serum tubes, but only a sterilized swab. This swab is planted on blood-serum as soon as it arrives at the laboratory, and examined after eighteen or twenty hours' incubation. A smear preparation is made from each swab after it is planted on blood-serum. The blood-serum is prepared according to the formula

of Löffler, and care is taken that it is always fresh.)

In 186 samples where diphtheria bacilli were found, 141 showed granular types and 45 barred types.

Type A was present in 39 cases.
Type B in three cases.
Type B′ in two cases.
Type C in 56 cases.
Type C′ in 40 cases.
Type D in 29 cases.
Type D′ in three cases.
Type E in 13 cases.
Type F in one case.

It is thus seen that type C is the most common one, then in decreasing order, C′, A, D, E, B, B′, F.

Type A was most commonly found in smears made directly from the swab. Variation of type was often observed, that is to say, in specimens made directly from the swab certain types were present while in the cultures, different ones were observed.

Not only the virulence of the bacilli but also the quality of the medium and the number of days that elapse before the swab is examined and planted may have some influence on the types present.

I shall endeavor to keep a record of the different types during this year and ascertain, if possible, the virulence of the most common ones.

INTERMITTENT CLAUDICATION AND ANALOGOUS PHENOMENA (ANGINA PECTORIS, ETC.).[1]

BY ARTHUR J. PATEK, A.B., M.D.,
OF MILWAUKEE, WIS.;
ADJUNCT PROFESSOR OF MEDICINE, WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS.

IN presenting this paper to you I am actuated by two motives—one the report of a rather infrequent symptom group that occasionally attends a disease of great frequency, general arteriosclerosis, but more often exists independent of it, the other—to dilate in some detail upon the more recent inquiries into the causation of stenocardiac attacks of which angina pectoris is the best known type. I desire first to present my notes of a case of intermittent claudication, and I trust this unusual condition will prove to be not without some interest.

Personal History.—The patient is a retired merchant. Until the age of sixty he was active in business and in fair health. Ever since a young lad he has complained of a weak stomach, but with this exception he had no illness that may have a bearing upon his present condition. Syphilis and excessive alcoholic indulgence are denied, though I have learned from other sources that he was formerly by no means moderate in the use of spirits. The gastric disturbance has been a source of constant complaint, and is limited to a feeling of distress after eating.

He has been an invalid for several years past, has traveled extensively in search of health, has been to various spas; but his condition remains, with slight exception, stationary, and at present differs but little from that obtaining for several years. The whole picture as presented now has come in so gradual a sequence that it will be quite sufficient to detail existing symptoms.

Status Presens.—The patient easily shows his age of seventy-three years. He is sallow, his skin has a pasty, yellowish hue, and while he seems at times rather listless, his eyes brighten in conversation and his mind becomes alert and active; his temperament—so far as opportunity has been afforded me to judge of it—is a rather happy one; he constantly recalls interesting happenings of his early years, is pleased with happy reminiscences, and enjoys the telling of jokes and humorous events of his life. At the same time he is rather outspoken and severe with those attending him, though this—I am told—was his habit when in business also. His mind has always been clear, and his memory most excellent, nor has this undergone any marked deterioration. Subjectively he complains of gastric discomfort and a rather harassing cough, with some expectoration. In addition he finds walking difficult; his limbs feel heavy, and a dragging of the legs is apparent; there is at times a considerable degree of weakness in the lower extremities, and it frequently happens that, when rising from a sitting posture, he is compelled to take hold of some object or person to prevent his falling. This latter symptom, however, is due—not so much to weakness of the limbs as to a dizziness that comes over him, and frequently his body will sway perceptibly before he finds a safe and firm foothold upon the floor. Then he can usually proceed, though never without the support of a cane. It happens, too, and this is the symptom to which I desire to call attention, that, while walking with comparative ease for a few minutes—he suddenly experiences a sense of weight and a cramp-like pain in his legs; then they give way underneath him and he falls to the pavement, helpless. After a few moments' rest he can rise and proceed. He rarely has more than one such paroxysm, because—knowing his infirmity—he never ventures far from home.

Objectively we find of interest the following conditions: a waxy, sallow complexion and poor muscular development; hearing is dulled; sight is good with the aid of spectacles, bilateral arcus senilis is prominent. Signs of chronic bronchitis with emphysema are present, the latter not very pronounced. The cranial nerves are intact with the exception of the right hypoglossal; the tongue occasionally deviates perceptibly to the left, and is at times complained of as being heavy and unwieldy; this, associated with a weakness of the arms and legs predominating on the left side, indicates the existence of a cerebral lesion, though

[1] Read at the Fifty-eighth Annual Meeting of the State Medical Society of Wisconsin, Milwaukee, June 23, 1904.

in the absence of a seizure of any kind, neither patient nor attendants were aware that a hemiparesis existed. Tactile, thermal and localization sense are normal. The knee reflexes are reduced on both sides, ankle elonus is absent, skin reflex normal, pupillary reflexes sluggish. Coordination is fairly well preserved, Romberg symptom absent. The viscera show the following changes: The heart is somewhat enlarged generally, the mitral systolic sound is indistinct, occasionally lengthening out into a sort of murmur, but the diastolic basal sounds are not appreciably accentuated. The lungs give evidence of a chronic bronchitis with emphysema. The liver is of normal size, spleen likewise. The urine is said to have contained hyaline casts and albumen, but is now free from either of these constituents. The daily quantity passed averages 60 ounces or more and has a low specific gravity.

The radial arteries are hardly more resistant than normal. Pulsation is present in the dorsalis pedis artery, but *absent in both posterior tibials at the internal malleolus.*

The whole clinical picture, with widespread lesions, consisting principally of cerebral symptoms—general and local—and involvement of the heart, kidneys, and to a slight degree the superficial vessels, allows of but one interpretation—a general arterio-sclerosis, or arteriocapillary fibrosis. The one symptom, however, to which our attention is called, is the cramp and loss of power in the lower limbs, coming on without premonition and of brief duration: this is known technically as "Intermittent Claudication" (limping).

History of Disease.—Intermittent claudication had been recognized as an affection of horses many years previous to its recognition in man. A French veterinarian, Bouley the elder, gave the name in 1831 to a peculiar disease occurring in horses, found to be due to an obliterating endarteritis of the crural vessels. An animal, so affected, trots upon demand, but in about fifteen to twenty minutes it limps, stops, and is unable to move, its legs are spread apart, and, though urged on, it falls to the ground, rigid and helpless, and in apparent agony. Upon rising it continues to trot for a brief distance, when a similar paroxysm again throws it to the ground.

To Charcot[1] belongs the credit of first placing this symptom-group as it occurs in man upon a recognized clinical basis. In a clinical lecture on "Intermittent Claudication and Diabetes"[2] delivered at the Saltpêtrière in 1887 (Leçons du Mardi à la Saltpêtrière) Charcot reminisces as follows: "One day—a long time ago—in 1855 or 1856, I was then an interne in the service of Rayer—one of the patients told me that he could not walk longer than a quarter of an hour without being taken with a cramp in his lower extremities; he would rest, then begin to walk, and the cramps would recur. This man died, and I had an opportunity to make an autopsy and account for this bizarre symptomatology of which I had never before heard mention—which shows that one does not appreciate thoroughly all that one sees, for certainly these cases are not very rare; I know to-day of a number of them. The fact is that at the autopsy I found—curiously enough—a bullet encysted in the neighborhood of the iliac artery, which bullet our patient had received at the siege of Alger, in which he had taken part. You see that was a long time ago, for he died at the age of fifty-six. He received the bullet in the back, and it was impossible to follow its course. I found it in the abdominal cavity; it had struck the iliac artery, causing a traumatic aneurism which had obliterated the artery in its lower part. Collateral circulation had been established, and the arterioles, which normally were very small, had become voluminous, and were of such a character that the blood flowed freely when the patient was in repose; but when—and here is the mechanism of intermittent claudication—the limbs were fatigued by walking, the quantity of blood distributed to them was insufficient, a relative ischemia setting in at the moment, this absence of blood causing numbness, cramps, and inability to continue walking."

It needs the clever observation of one whose watchful eye allows nothing to escape and whose analytical mind interprets logically, to call attention to a condition which, though uncommon, falls nevertheless within the experience of many a physician.

Literature.—Charcot found fault with physicians because of their apparent neglect of this affection. He remarks (in 1887): "Curiously enough, though my essay of 1856, presented to the Biological Society was written not in Chinese but in French—in good French at that—I I have not encountered a single physician who has taken notice of my observation." This was an unjust criticism, inasmuch as Leyden had in 1874 taken cognizance of Charcot's observation, and Erb in 1876. Sir Benjamin Brodie, in 1858, described the symptoms of intermittent claudication and referred to them as premonitory signs of senile gangrene. Aside from observations of Charcot's made at various times since his early report, there are a number of other references to this disease. A most exhaustive treatise on the subject has been written by Erb,[3] who reviews the history of cases reported, and cites *in extenso* the literature extant; his own personal observations in this report cover thirteen cases of which the salient points are detailed. But recently Erb[10] has published a record of 45 additional observations of this disease made since his first series of six years ago. Goldflam[4] reported six cases in 1895 and more recently[5] presented a study of 24 additional cases.

A number of others are reported from various foreign sources, making a grand total of 127, of which 120 are males.

American literature is apparently very meager,

for I have been able to collect but three cases, one each described by Riesman[6] and Gordon,[7] of Philadelphia, and Levy,[8] of Syracuse. Gordon's was not a case of pure intermittent claudication.

Symptomatology.—The development of the symptoms usually present may be briefly described as follows: paresthesias in the feet; then vasomotor disturbances, such as blueness, redness, pallor, or coldness of the feet; next the motor symptoms as described: walking becomes difficult, it is found impossible to proceed because of a rigidity or painful cramp in the legs; after a period of rest locomotion may be resumed, only to find the paroxysm returning after a brief time.

Although intermittent claudication is a characteristic and frequent symptom of arteritis—this being the pathological condition, as we will find—it may be absent entirely, and the arterial disease be manifested by pain arising spontaneously in a condition of rest, and independent of walking. This pain may be in the calf, along the sciatic nerve, in the sole or toes, or there may be but little pain and merely a sensation of weariness and formication. In such cases *the absence of the arterial pulse in the foot is the diagnostic feature.* The symptoms mentioned have frequently led to erroneous diagnoses of sciatica, neuralgia, and rheumatism. When the arteritis—which is a progressive disease and involves progressively larger areas—has advanced to a marked degree, there will be present—in addition to the typical symptoms—attacks of pain, even when the limbs are at rest. Occasionally the disease seems to arrive at a certain degree of severity and then remain stationary.

My patient has practically no pain while resting in bed, and enforced rest brought on by a severe attack of sciatica has put the other symptoms in abeyance. His condition is not progressing.

Objectively, some signs of disturbed circulation are usually present: superficial dilated veins, cyanosis, edema, cutaneous petechiæ, phleboliths, and phlebothromboses. The muscles are at times sensitive to pressure, atrophy may take place, and active fibrillary contractions are seen. But more important than these vasomotor and other disturbances is the circumstance that *pulsation of the dorsales pedis and tibiales posticæ is frequently either entirely absent, or can be appreciated with difficulty*, and the rigidity of these vessels can frequently be determined. Of the 24 cases reported by Goldflam, pulsation in both dorsales pedis arteries was absent in 13, on one side only in 10, while both were weak in but one case. Both tibiales posticæ were pulseless in seven, one artery only in eight, and in the remaining nine pulsation was present.

Of Erb's recently reported 45 cases, 30 were bilateral, 15 unilateral. Of the 30 bilateral cases, pulsation in all four pedal arteries was absent in 16 cases, three were absent in two cases, two in seven cases, and in only one case was the absence of pulsation in a single artery noted. In four typical cases all four arteries pulsated perceptibly. In 13 of the 15 unilateral cases, pulsation was absent in both anterior and posterior tibial arteries. In my case both dorsales pedis arteries pulsate, but the tibiales posticæ do not. These cases demonstrate the frequent association of this symptom with the disease under consideration, and serve to emphasize its diagnostic importance, more particularly when the unmistakable classical symptoms are not present. In 37 of Erb's second series of 45 cases other unmistakable signs of arteriosclerosis were in evidence.

While in most cases recorded the symptoms are bilateral, the disease has been encountered affecting but one limb. In these cases the dorsalis pedis and posterior tibial arteries pulsated in but one limb, but where the symptoms occurred symmetrically pulsation was either absent or slight. Because of the fact that the limping is not a constant feature of all cases, Erb suggests a name based upon the clinical and pathological features, "Dysbasia Intermittens Angiosclerotica."

Analogous Phenomena.—Weber[9] describes the case of a man whose left common iliac artery was obliterated by accident, and who suffered from muscular cramps in the left leg, but unaccompanied by other features of intermittent claudication.

Nothnagel has described analogous phenomena of the upper extremity.

Charcot called attention to the similarity of the symptoms to those of angina pectoris in the sclerotic occlusion of the coronary arteries; in fact, one of the cases of intermittent claudication coming under Charcot's observation, died of angina.

There are cases of milder symptomatology, as we know, due to sclerosis of the coronaries or the first portion of the ascending aorta, in which the symptoms are about as follows: the patient,—while walking—is suddenly taken with a pain beneath the sternum, radiating to the epigastrium and into the back, associated with great anxiety. After a rest of a few minutes he can proceed, though there is danger of a repetition upon exertion. A hearty meal may also bring on an attack. These are cases of "angina d'effort" (angina following effort)—with a true claudication of the heart.

J. Schnitzler[12] reports a symptom-complex which he terms "Intermittent Ischemic Dysperitalsis"—an intermittent painful peristalsis on an ischemic basis. The symptoms in his case were those of excruciatingly severe intestinal cramp-like pain, with distention, and without any symptom of obstruction. The symptoms were found to be due to thrombosis of the superior mesenteric artery, the result of arteriosclerosis. He draws a parallel between this condition and that of intermittent claudication. Others have since then made similar observations.

Breuer[13] reports two such cases. It is probable that the severe attacks of colic that have been

recorded by various observers as symptoms of thrombosis of the intestinal arteries, are in reality to be ascribed to this "ischemic dysperistalsis"—to use Schnitzler's term. Breuer calls attention to the fact that in the reported cases of aneurism of the mesenteric vessels, and more particularly in the cases of aneurism of the aorta in the neighborhood of the superior mesenteric artery, there were noted long and severe colic-like intestinal pains. Collateral circulation will—in all such cases—make these attacks infrequent for a time, but as soon as occlusion of the vessel is entirely or almost established, the symptoms ensue with severity and persistency. We might bear in mind that the pains of syphilitic arteritis are of vascular origin.

There are doubtless other cases of arteriosclerotic pain that fall in the same category. Breuer cites the case of a patient who suffered severely from renal colic, supposed to be due either to a tumor or hemorrhagic infarct. Postmortem examination revealed neither tumor nor signs of an infarct, but a marked sclerosis of the renal arteries. Kaufmann and Pauli[14] made a careful study of stenocardiac pains in the epigastrium, and conclude that these cramp-like spasms are not primarily due to a relative ischemia of the part, but that an angiospasm of the partly sclerosed vessel determined the ischemia and pain.

Ortner[15] cites a case of angiosclerosis of the abdominal vessels (abdominal aorta, cœlic axis and mesenteric arteries) with symptoms of angiospasm—an intermittent claudication of the intestines.

Wagenmann (cited by Ortner) reports having observed with the ophthalmoscope an interesting phenomenon in a patient who had marked general arteriosclerosis. The patient complained of a periodic clouding of vision, and during such an attack Wagenmann distinctly observed a spasm of the retinal vessels. This may with justice be termed an intermittent claudication of the retina.

Having in mind that claudication seems, thus, to involve various organs, Ortner suggests that Erb's term "dysbasia" (difficult walking) I. A. be modified to "dyspragia" (difficult functionating) intermittent angiosclerotica: we may thus speak of a dyspragia of the extremities, heart brain, retina, kidneys and bowel.

Causation of Symptoms.—Charcot's explanation—and this applies to the analogous phenomena just stated as well—that when the limbs are at rest collateral circulation is well established, but when they are put to the exertion of walking, a temporary ischemia of the part followed by transient muscular spasm and paraplegia, sets in as a result of the sclerotic occlusion of the artery, is generally accepted.

This theory, however, that the arterial disease is the direct and sole cause of the pain and paresis in intermittent claudication as well as in angina pectoris—the symptoms being due to an ischemia of the muscles—a cry for food—is inadequate to satisfactorily explain these phenomena. This is possibly best understood if we call to mind the well known fact that the cases of angina pectoris are numerous in which there is but slight sclerosis of the coronary vessels, and vice versa—that stenosis of the coronary artery has been found in the case of persons never known to have suffered from angina pectoris.

In a number of autopsies made upon patients suffering from stenocardiac epigastric pains, Houchard (quoted by Kaufmann and Pauli[13]) found a condition of sclerosis but no anatomical narrowing of the blood vessels, and therefore, he too argued that an ischemia on this basis could hardly be a prerequisite of these attacks.

Weber[9] too—because of reasons mentioned—namely—that there is no constant interdependence of coronary sclerosis and angina pectoris—is disinclined to place credence in Charcot's explanation. He maintains "that muscular cramp does not take any part in angina pectoris or in the phenomena preceding senile gangrene in an extremity, but that cramp is likely to occur in any muscle where an accumulation of waste products takes place, whether this accumulation be caused in healthy animals by rapid catabolism due to excessive exercise (cramps following overexertion, as in athletes), or by insufficient removal of waste products in cases of disease due to stenosis of the main arteries and consequent diminution of the blood stream through the affected part."

We are indebted to Nothnagel for a solution that has an air of great plausibility, seems to be well substantiated by facts, and has of late received generous recognition. Nothnagel claims that the symptoms of painful spasm are of arterial origin, that the developing ischemia is due to an arterial spasm, the result of an effort on the part of a diseased artery to supply an increased quantity of blood, and that the pain is in reality a blood-vessel pain. Such an angio-spasm would—though the organic occlusion of the vessel be but partial—cause an absolute ischemia of the part nourished, and, as a consequence of this, severe symptoms follow. It is probable, too, that this angiospasm may be transmitted from its seat of origin to other vessels in continuity with it, and thus cause very extensive spasm, pain and ischemia. This is seen in cases of very sudden death in attacks of angina pectoris when but a small embolus or thrombus is lodged in a coronary artery, and is evidenced too by the radiation of the stenocardiac pain from the precordium into the vessels of the arm.

These considerations shed light upon the probable causation of this painful spasm—intermittent claudication, that is—arteritis plus arterial spasm, but of even greater interest is the light shed upon the possible causation of the symptoms of that very frequent affection, angina pectoris; certain it is that the cases of sudden death in which but a slight coronary sclerosis is found are numerous, and these, I believe, are best ex-

plained upon Nothnagel's theory of angiospasm which produces a relative occlusion of the vessels, and which, because of its transmissibility by continuity, may account for the radiation of the pain into the arm.

Complications: Gangrene and Diabetes.—The essential morbid changes that produce the symptom-complex intermittent claudication, being—as has been stated—a more or less complete obliterating endarteritis involving the distal arteries of the foot and leg, and frequently the femorals and iliacs as well, it occasions no surprise to learn that gangrene of the affected extremity occasionally supervenes. This has been frequently encountered, and appreciation of this danger is nowhere better expressed than in Charcot's words: "Each time that I saw these symptoms (intermittent claudication) appear, it has seemed to me that I could see beginning the second act of a drama of which one could, as time passed on, detect the evolution." Of Goldflam's 24 cases, seven terminated in gangrene. In these cases the paroxysms were unusually painful. I. H. Levy also cites a case with the same outcome. Charcot and others have called attention to the occasional association of symptoms of intermittent claudication with diabetes. When one recalls the frequency of gangrene—the result of the arterial obliteration—in the latter affection, the possibility of the development of this peculiar symptom-group is self-evident.

Etiology.—Etiology, the ready inference is justified that whatever causes act in producing arteriosclerosis elsewhere obtain here, too, and so we may include as factors in the causation of this affection: alcoholism, gout, lead, syphilis, tobacco, and exposure, the last three being the prominent factors in Erb's cases, special stress being laid upon tobacco abuse as a cause.

Erb asks the pertinent question (but leaves it unanswered): why—if arteriosclerosis is so very common—is intermittent claudication so relatively rare, and what is it that determines the development in these cases—as points or predilection—of this sclerosis in the limbs? In one of Erb's cases there was no distinct evidence of sclerosis of the radials, temporals, carotids or heart. This applies in a measure to the case I report, though it is quite evident from the history and symptoms that the vessels of the internal viscera are affected.

Diagnosis.—There are two diseases with which intermittent claudication may at times be counfounded, these being erythromelalgia and Raynaud's disease. Pathologically they are very similar, for all are due in part at any rate to vascular changes, and a thickened intima is constantly found. The difficulty of distinguishing these three diseases is heightened by the fact that their symptoms are often very similar, and because combinations of the affections apparently exist (Cassirer[10]). The case reported by I. H. Levy had vasomotor symptoms suggesting an erythromelalgia.

Mitchell and Spiller,[11] in their report upon the miscroscopical examination of the tissues of an amputated toe from a case of erythromelalgia, report finding, in addition to degeneration of the nerves, marked proliferation of the intima and media of the vessels, and in some sections almost an occlusion of their lumen.

The most prominent symptoms that differentiate intermittent claudication in its pure form from other affections, are the intermittent character of the paroxysms—absent when the patient is at rest, and produced only by walking—and the absence of pulsation in one or more of the distal arteries.

The diagnostic importance of the latter symptom is well demonstrated by Erb. Examinations made upon 700 individuals who were presumably not suffering from grave heart or vascular disease, or such conditions as edema, eczema or elephantiasis that would make palpation difficult, indicate that the pulsation of the dorsalis pedis and posterior tibial arteries can normally be felt in 99 per cent. of all cases. It does not follow, however, that the absence of pulsation results in the symptoms mentioned, because appreciation of the pulsation may be impossible, and this be due only to a rigid and not entirely occluded vessel; again, even though it be occluded, an established collateral circulation may prevent further symptoms. Furthermore, one of Erb's cases teaches him that the symptom-group—intermittent claudication—may be present without the absence of pulsation in any one of the four vessels.

Treatment.—Intermittent claudication is not a disease *sui generis,* but merely a peculiar clinical manifestation of arteriosclerosis involving the vessels of the lower extremities. Appreciating its pathology, an early recognition of the import of the symptoms is made manifest, in order to anticipate and prevent, if possible, complete arterial obliteration, and foretell a probable gangrene consequent upon such occlusion. That the disease has been insufficiently recognized before such a complication set in is undisputed.

The measure of comparative safety lies in the establishment of a satisfactory collateral circulation, or even re-establishing a channel in the occluded vessels—in order to improve the nourishment of the limb. Therefore bodily rest with warmth and moisture is an all-important element. If a suspected or probable cause is known, this must be corrected at once. The diet must be attended to and the personal hygiene regulated.

The use of alcohol and tobacco must be interdicted, and all excesses and abuses avoided. Hydropathy, massage and electricity seem to have been of service in some cases. Among drugs the iodides, vasodilators and heart tonics are indicated. Goldflam found the iodides of questionable value. Theobromine in the shape of diuretin has of late been advocated as relaxing vasomotor spasm, and would theoretically be indicated. In the main, however, one must rely on

a therapeusis of general character, not medicinal. When walking is to be resumed it is to be done with the utmost caution to avoid undue fatigue.

Both Erb and Goldflam report cases that were relieved of all symptoms, some in which pulsation returned in the crural vessels, and other cases that were markedly ameliorated. In the case reported above faint pulsation can now be felt in the right posterior tibial.

CONCLUSIONS.

The study of the cases of intermittent claudication thus far recorded justify the formulation of the following conclusions:

1. Intermittent claudication is far more frequent symptom-complex than generally recognized.

2. It is doubtless frequently and freely confounded with sciatica, neuralgia and rheumatism.

3. Careful and detailed inquiry into the symptoms which usually come on while walking and are absent when at rest, together with their intermittency should lead to a suspicion of the diagnosis; this will be made absolute by finding that

4. Pulsation is absent in one or more distal arteries (dorsalis pedis and tibialis posticus) of one or both legs.

5. The pain is of vascular origin and due to an arteritis plus—in many cases—angiospasm of the affected vessel.

6. The various internal viscera may suffer from such an angiospasm when their vessels are sclerosed, the most prominent prototype being the heart in the common condition, angina pectoris.

7. Total occlusion of the vessels, as occasionally found in intermittent claudication, may lead to gangrene of an extremity.

8. Early recognition is essential, in order, by appropriate treatment, to prevent this dire and frequent complication.

New York Polyclinic. Emeritus Professor H. Newton Heineman will deliver a lecture at the New York Polyclinic Medical School and Hospital on Monday, December 5, 2.30 P.M., through the courtesy of Professor Manges. The subject of this lecture is to be "The Nauheim Treatment of Heart Disease."

MISOCAINIA IN MEDICINE.

BY ACHILLES ROSE, M.D.,
OF NEW YORK.

Lombroso has called the deep rooted inclination of mankind to combat new ideas "misoneismus." For this barbarous term let us substitute a correct name: "misocainia."

In medicine, as in other sciences, many new things are brought up from time to time which, later on, are recognized as new errors; this explains why new ideas are received with caution, even with suspicion; but this is nothing morbid and cannot rightly be called misocainia. We can speak of misocainia only when the motives of the opposition against new ideas are prejudice, selfishness, and indolence—the archenemies of all progress—and we may classify misocainia as phrenitis *sui generis* in cases in which it develops to such a degree that men of science, of exalted position, lose the sense of truth and honor and degrade themselves by the employment of unworthy means in order to suppress a new idea or intrigue against and injure those who have promulgated a new truth.

Of this form of phrenitis examples exist in the history of medicine.

John Kanold, in the year 1708, wrote: "It is to be hoped that at this time no one who has common sense will deny that the *historia morborum* is the most important and most valued support of the whole of medicine, because, by thorough knowledge of this history, we learn to arrive at the true pathologico-etiologic conception and consequently we find the necessary and reliable *indicationes curativæ*.

Nothing in the world has caused more animosity, more persecution, than the promulgation of new religious doctrines, but the cruelties originating in religious fanaticism are more easily explained than the rage of men of science against new ideas.

While the ecclesiastical courts of several countries had hundreds of thousands tortured, burnt at the stake; while for centuries, even in America, unfortunate women, supposed to be witches, were drowned, there is no case known in which a physician, for the promulgation of a new scientific truth, has been tortured or burnt at the stake.

The fact is that a physician, Servatus, the discoverer of the pulmonic circulation, a forerunner of Harvey, was burnt at the stake on October 27, 1553, at the instigation of Calvin. His agony was prolonged in a most cruel manner by keeping the fire low. After he had been for half an hour on the burning stake the unfortunate man asked to have more wood applied to the fire, that death at last might relieve him. But Servatus did not die a martyr to science; he was the victim of religious persecution, because he had expressed an opinion about the holy Trinity which differed from Calvin's teaching.

The case of Galileo may be mentioned here, as it offers an opportunity to expose one of the most pertinacious historical lies. The story that Ga-

lileo had been tortured is found in school books, and it is difficult to eradicate it.

Galileo had studied medicine; he was a physician, although he devoted himself to study of mathematics, astronomy, and the natural sciences. He made many enemies by mixing quite unnecessarily theological controversies with his astronomical discoveries. It is true that he was brought before the tribunal of the Inquisition, but the legend of his torture is an invention. Whatever accusations against the clergy for their intolerance may be justified, towards Galileo they acted rather generously.

In fact, there is no case known of a physician being tortured or burnt at the stake on account of a scientific discovery.

Johann Baptista van Helmont, born in Brussels, in the year 1578, one of the greatest scholars among the physicians of his time, the discoverer of carbonic acid, wrote against a certain sympathetic remedy. For this he was taken before the Archbishop of Mecheln and punished with two years' imprisonment, because he had denied the healing power of religion. His colleagues called him all sorts of names because he was opposed to blood-letting, the universal remedy for almost all diseases at those times. Gui Patin wrote the following necrology: "Van Helmont étoit un méchant pendard flamand, qui est mort enragé depuis quelques mois. Il n'a jamais rien fait qui vaille. J'ai vu tout ce qu'il a fait. Cet homme ne meditoit qu'une medicine toute de secrets chimiques et empiriques, et pour la renverser plus vite, il l'inscrivoit fort contre la saignée, faute de laquelle pourtant il est mort frénétique."

During the period of the scholastics natural science was subordinated to, was the slave of, theology. The new fetters which Protestant orthodoxy wound around natural science were as tight as the old ones. Dogmata of the church exerted a great power.

In the year 1640 Juan del Vego introduced Calisaya bark into Europe. The new remedy became at once the object of much dispute. Because the Jesuits recommended and praised it, it was called *pulvis Jesuitarum*, and this name was enough to make it disliked among the Protestants. Physicians were against it because it cured intermittent fever too quickly, depriving them of a certain amount of income.

Physicians were too humane to manifest their intolerance by fire, as did the church; they went to work in a more subtle way, but they were cruel all the same, and after all they imitated to some extent the example set by the church. The object of the inquisition was to exterminate heresy, but as the fine humoristic expression was "without bloodshed," the heretics were burnt.

There were neither bodily torture nor stake for men of science who promulgated a new truth that was apt to harm the prestige of the authorities of the day; these men of science were tormented until they became ripe for the phrenocomion The misocainistai of the medical profession were like the clergy, "no blood shed;" they only differed in so far as they applied no bodily torture and did not burn their victims at the stake; they simply drove them to insanity.

The history of Harvey's discovery is too well known to need recapitulation here.

Harvey's book on the circulation of the blood is the earliest and most brilliant fruit of the method, founded by Bacon, of exact research in natural sciences. In regard to time it is one of the first products and in regard to value the greatest product of English medical literature, written throughout in a genuine scientific spirit.

Quite recently there appeared an editorial in one of our medical journals, according to which Harvey was not at all the discoverer of the circulation of the blood, and his book, this immortal work of Harvey, was called "verbose and somewhat muddled."

Es liebt die Welt das Strahlende zu schwärzen,
Und das Erhabene in den Staub zu ziehn.

Harvey had many opponents, but he did not, with one exception, answer their attacks; being thoroughly convinced of the truth of his teachings, he left it to time that he should be understood, and yet in the evening of his life he had the satisfaction of seeing his teachings adopted.

What the masses thought of Harvey's exertions we learn from the fact that after the publication of his work on the circulation his practice fell off; he was considered of diseased mind. The excitement Harvey's discovery caused in medical circles, and among the educated in general, was most extraordinary; epecially were physicians disgusted with a new thing which they considered of no value for the practice.

Würtz, who was far ahead of his time, must also have met with misocainia. He writes: "All sensible surgeons will excuse this, my writing, and easily admit that among the ancients there must have existed much ignorance and great stupidity as well as in this, our own time."

Leopold Auenbrugger discovered, in the year 1754, that the different kinds of sounds heard on percussion of the thorax, furnished an aid to judge the condition of the organs of respiration. His immortal work "Inventum novum ex percussione thoraci humani ut signo abstrusos interni pectoris morbos detegenti" appeared in the year 1761, simultaneously with the work of Morgagni, by which a new era of pathological anatomy was inaugurated.

Percussion shared in full measure the fate of most of the great discoveries. Of the few who took notice some treated it with indifference, some, and among them especially the Vienna physicians, with decided animosity, with disdain and ridicule, or with senseless contradictions. Haller was the first who openly expressed himself in its favor. In his review of Auenbrugger's book he said: "All such propositions, although they need not at once be accepted, merit to be listened to with respect." To Ludwig, of Leipzig, is due the credit of having been the first to recognize,

in 1763, the importance of Auenbrugger's discovery to its fullest extent; he spoke of percussion as the light which should banish the darkness that covered the diseases of the thoracic cavity.

It was reserved for mioscainia in the nineteenth century to drive two of the great investigators in medicine into the lunatic asylum.

Julius Robert von Mayer is the originator of the doctrine of the conservation of energy. In different publications he demonstrated the law of the indestructability of force. For the first of these he had to pay the expenses of printing, as no publisher would assume the risk. He was the first to grasp the conception of the equivalence of exertion and heat; he enunciated this principle with clear distinction; applied it, with great acumen to astronomy and to human physiology, furnishing conclusive evidence for his teachings. His labors did not meet with the approval they so richly merited, and the contradictions, the attacks he had to suffer, drove him to insanity. From 1852 to 1854 he was an inmate of the lunatic asylum of Göppingen, where he was treated, according to the old fashion, with locked chair and straight jacket. Dismissed as cured in 1854, he gradually had the satisfaction of seeing that his discovery was appreciated to its full value in all scientific circles.

Ignaz Philipp Semmelweis was born in Ofen, July 1, 1818. At nineteen years of age he began the study of medicine and graduated in Vienna in 1844. At first he devoted himself to general medicine under the inspiring influence of Skoda. In 1846 he became assistant in the first obstetrical clinic of Professor Klein. In this clinic there had been for many years an enormous mortality from puerperal fever reaching in one year so high a total as 31.3 per cent.

These disastrous conditions worried Semmelweis day and night. At that time there existed an abundance of theories to account for them, the peculiarity of which we shall understand when we consider the state of medicine in general at that period. Among the supposed or named causes was the transposition of the milk or the rising of the milk to the head, or milk metastasis; some accused cosmic or telluric influences, without assigning any reasonable definition of their meaning. Some explanation, however, had to be constructed in the absence of any definite ideas.

In the year 1847, the pathologist Kolletschka died. At post-mortem examination he had received a punctural wound of the finger and had succumbed to the pyemia which followed this accident. The details of this case of pyemia after wound disease corresponded exactly with all that Semmelweis had observed at necropsias of women who had died of puerperal fever.

As happens with the true genius, he found as quick as lightning the explanation which had been sought in vain for a long time: puerperal fever is caused by wound infection, it is pyemia proceeding from the wounded inner surface of the uterus. Not the wound itself but its infection is the external cause. Physicians and students, in the course of examination, by their unclean or insufficiently cleansed hands, transmit the noxa to the healthy but wounded woman. This seemed to him in accord with the observation that decomposing organic matter may cause decomposition and putrid infection in the living organism. He demanded that the hands should be disinfected with chlorate of lime water. This is in the main what he communicated as the result of his first researches. The greatest discovery in obstetrics, which has also become a far-reaching blessing to surgery, is connected with the name of Ignaz Philipp Semmelweis.

It is true that Semmelweis had forerunners; in the year 1831 Cruveilhier called women wounded while in the puerperium, and thought it possible that puerperal infection might proceed from their wounds. But how little impression this had made can be shown by the fact that the Academy of Medicine of Paris pronounced itself decidedly against Semmelweis in the year 1851, and again in 1858. Eisenmann and Henle, both pioneers of the parasitic theory of infection diseases and both too little appreciated, as also Denman, must, next to Cruveilhier, be named as real forerunners of Semmelweis. It is remarkable that in the many publications on Semmelweis which appeared in Germany, especially during the eighth decade of the nineteenth century, the American, Oliver Wendell Holmes, is not mentioned. Holmes had spoken on the etiology of puerperal fever in a manner similar to that of Semmelweis before a medical society, in April, 1843, and had suffered, before Semmelweis, the most violent attacks by the authorities of his day. His discovery and the injustice done to him have been described by S. Baruch. His history is so well known by us that I need not enter into details.

But even the forerunners had, as Semmelweis remarked, recognized only a part of the truth, not the whole truth. The revelation of this latter was reserved to Semmelweis. The nearest to him was undoubtedly our Oliver Wendell Holmes.

As a result of observing the precautions which Semmelweis thought necessary, the mortality in the first clinic became reduced to 3.08 per cent.

Very soon Semmelweis found that cadaveric poison (ptomain) was not the only noxa producing puerperal fever, but that, in general, ichor from living organisms or air impregnated with ichorous particles caused infection. To him the decomposed organic substances were the carriers of infection.

The misocainistai accuse the discoverers of a new truth of having said things of which in reality they never thought. This feature was noticed when Niemeyer's book appeared in an English translation in 1870. Long after Semmelweis had said that cadaveric poison was not the only carrier of puerperal infection, his opponents, Scanzoni, Braun, Späth, Breisky and others, continued to accuse him of having spoken

of no other means of infection, and they gave him the nickname of the "cadaver apostle," and said that he was a very one-sided physician whose results were of the most meager significance. Semmelweis, in 1848, improved his method, which at first consisted solely in disinfection of the hands, in so far as that he insisted that not only the hands of the examiner but also the instruments and the dressing material, should be disinfected beforehand, and that patients with puerperal fever should be separated from those who had not been infected.

In this year, when strict and general disinfection was carried out, the mortality from puerperal fever in the first clinic sank still lower namely, down to 1.27 per cent., notwithstanding that examinations continued to be made by students.

Now, for the first time, Semmelweis came before the profession, speaking to the Vienna physicians, who were well aware of the former fearful condition, of his results.

One would have expected that when Semmelweis placed these plain figures before them and explained his views with great clearness and simplicity, all would have applauded him.

It is true some of the best men, Hebra, Haller, Skoda and Rokitansky, coincided with him without hesitation or reserve, but the representatives of his specialty, the obstetricians (with the praiseworthy exception of Michaelis, of Kiel) and especially his superior, Klein, opposed him, and took decided part against him.

In the oration of Ferdinand Hüppe, at the dedication of the Semmelweis monument before the Eighth International Congress for Hygiene and Demography, at Budapest, September 2, 1894, of which oration I have availed myself to some extent, he says: "Egoism, jealousy, fear of humiliation in view of the former miserable conditions, the dislike to abandon some nonsense to which they had become attached, the necessity of having to acknowledge their own gross mistakes, all these things manifested themselves by the actions of an omnipotent caste of bonzes toward the genius."

This was misocainia, that form of misocainia which borders on infamy. It is a distinct form of phrenitis.

At that time Semmelweis applied for a professorship: his enemies, however, frustrated his plans in this direction. The leading men in obstetrics in those days, Kiwisch, Scanzoni, Seyfert, Hammernick, had formed a conspiracy against Semmelweis.

But after all, a truth, new or old, cannot be suppressed without great exertions. In Vienna other men, Chiari, Helm, Arneth, stood up for Semmelweis, and in the year 1850 it seemed as if he had been victorious in Vienna. But this did not suit Klein and his partisans. They agitated to have him debarred by the States Ministry, and they succeeded. Semmelweis could find no place in Vienna. Deeply pained by such ingratitude he left and went to his native city, Budapest.

The want of animation, the obligation to care for the daily necessities, made him silent, and his silence caused his friends to halt in their zeal and their agitation for his cause.

His enemies, however, remained active, and the cities of Vienna and Prague secured for themselves the melancholy renown of having successfully combated the greatest and most beneficial discovery in obstetrics.

Thus the universities of Germany, and especially Vienna and Prague, were eager to suppress, by means of detestable star chamber practices, the most genial obstetrician in history.

At last, in the year 1855, the great investigator was honored by the Hungarian Government according to his merits. Without any step on his part to secure the position, he was made professor of obstetrics at the university of his native city. Here he enjoyed some years of happiness. A professorship at the university of Zürich was offered but was declined by him.

Scanzoni, Braun, and Späth continued to defame Semmelweis. Again and again they accused him of having spoken of the cadaver poison as the only carrier of puerperal infection. It is most remarkable how the misrepresentations and errors of Scanzoni are long-lived, most persistent in literature and tradition. As late as 1870, physicians of Berlin spoke of Semmelweis as the cadaver apostle, and even at this present day there are some, who have read only one part of the literature, who say Semmelweis had not been appreciated in lifetime because he had persisted in attributing puerperal infection solely to cadaveric poison. It is the same case with Scanzoni's error about the danger of carbonic acid gas inflation. It seems impossible to eradicate the errors of Scanzoni.

The moral deficiencies of his adversaries—misocainia sometimes suspends morals—were attacked by Semmelweis in a severe manner.

The open letters which he addressed, during the years 1861 and 1862, after the publication of his book on the etiology and prophylaxis of puerperal fever, to several prominent obstetricians and to all the professors of obstetrics who refused to grant him a hearing, and whom he called murderers, are well known. It cannot be denied that the tenor of these letters far outsteps the customary bounds of restraint, but no reproach on this account is due from his detractors to the man whom they had so greatly hurt. The tenor of his indignation corresponds with the baseness of the character of his opponents. Their celebrated open letters serve to show how bitterly he had been attacked and what tortures he must have endured.

"The deplorable conduct of his opponents" says Hüppe in his oration, "is the more inconceivable, as many among them had accomplished original work of lasting value in other branches of obstetrics, so that there existed no danger of the lessening of their fame." The explanation is that they were afflicted with intractable misocainia.

In the year 1861, Semmelweis had collected all his writings in his work on "The Etiology, Conception and Prophylaxis of Puerperal Fever." This work is one of the real classics of medical literature.

Completed in some details, with the addition of statistical evidences, but without any essential changes, he gives the views already presented in 1847 and 1848.

In accordance with his ideas in regard to etiology he demands in case of autoinfection all that we now call "antisepsis," in all other cases on the part of the operator cleanliness and disinfection of the hands, the instruments, the dressing material, the clothing, that is, all that we now call "asepsis."

This work had at first, thanks to the conspiracy of his enemies, almost no success. Scanzoni, Braun, Späth, Breisky and others, continued to call him the cadaver apostle. Only Lange, of Heidelberg, Kugelmann, of Hanover (the latter in writing to Semmelweis expressed "the holy joy" he had experienced when reading the book and calls Semmelweis a second Jenner), Hirschler and Markusovsky, of Pesth, stood up firmly for him, while on the occasion of the Thirty-sixth Congress on Natural Sciences, at Speyer, not only the obstetricians present, with the exception of Lange, but also Virchow were against him.

One of the most highly praised and most instructive books in medical literature is the work of the great surgeon Pirogoff, on the errors he committed in his surgical practice. Indeed we may learn as well from the errors of great men as from their correct ideas. Virchow's error teaches us not to trust too much to authority. However highly we esteem Virchow, we cannot omit speaking of his mistakes when writing medical history.

In the year 1864, the Bohemian parliament wished to hear the opinion of experts on puerperal fever, and lying-in institution buildings. Oppolzer, Rokitansky, Skoda, Virchow, Lange, Schwarz, Heckner, and Löschner were the experts selected. Oppolzer, Rokitansky, Skoda and Lange expressed themselves in accordance with the principles of Semmelweis. Virchow's opinion read as follows: "The *main cause* of the rise, development and spread of puerperal fever, is an individual *predisposition* to diffuse and malignant forms of inflammation; puerperal fever can set in in consequence of this predisposition solely, *without any contagion*. Local specific infection, contagion, happens only when the epidemic is at a certain high stage and when the contagion is of a certain intensity. In individuals without predisposition the contagion may remain ineffective."

As late as the year 1874 Virchow, but very conditionally, pronounced himself in favor of the parasitic theory.

Of the pathologist-surgeons of that time, that is from 1860 to 1867, only Roser promulgated views which came near those expressed by Semmelweis, but they were also attacked by the leader in pathology, Virchow, and by his adherents, Billroth and Weber.

That the results could not be everywhere and at once favorable we can understand now, when we consider that the technics had to be learned first, and that it was only later on that bacteriology brought full clearness in the understanding of most details.

This is an excuse to be made for those opponents of Semmelweis who had honestly tried his method. Where such honesty is wanting, as in the cases of Braun and of Scanzoni, where the requests were executed with no good will and imperfectly, the unsatisfactory results and the return of epidemics are not to be wondered at. Misocainia will not allow any good results, any success to a new idea, and no means are too base to suppress the new idea.

It was not granted to Semmelweis to see the triumph of his teachings. He became more and more irritable, and when he had addressed lay people in the street, to whom he said that they were not prejudiced like the professors, and to whom he explained his theory, he was taken to the lunatic asylum, and there he died on August 13, 1865, in his forty-seventh year.

Twenty-nine years after his death, physicians from all parts of the world united in erecting a monument in his honor, to commemorate the services rendered by him to science and to mankind.

Misocainia, so long as it is not manifested in a dishonorable manner, is natural, but misocainia expressed in malevolent misrepresentations is phrenitis.

I have undertaken to call attention to the rôle misocainia has played in the history of medicine. I had neither time to enter deeply into the subject, nor was I prepared for such serious historical studies. I hope, however, that this little collection of examples will be of interest and will aid in giving light on a remarkable form of phrenitis, and that the knowledge of the facts enumerated will be of some usefulness.

A NEW CASE OF CHLOROMA WITH LEUCEMIA, WITH A STUDY OF CASES REPORTED SINCE 1893.

BY GEORGE DOCK, M.D.,
AND
ALDRED SCOTT WARTHIN, M.D.,
OF ANN ARBOR, MICH.

(Continued from Page 1032.)

This conception of Kundrat seems difficult or even impossible to accept literally, on account of the numerous connecting links between it and the very diseases that Kundrat separated from it, and also because of the older and equally unsatisfactory use of the term lymphosarcoma.

Rosenblath emphasized the difficulty of classifying chloroma among lymphomata on account of the tendency of the latter to remain within the capsule of the gland and not form metastasis.

"In chloroma even the tumors of the orbit, which seem at first glance to act like lymphomata, are quite different. They have no capsule, and grow through fat, nerves, and muscles. The majority of the other larger tumors are closely united with the periosteum and grow diffusely." Clinically and microscopically he thought chloroma grows very differently from leucemic and pseudoleucemic lymphomata, but he recognized the intimate relationship between chloroma and leucemia, and admitted that the histologic structure differed from that of sarcoma.

Risel, who made the anatomic examination in one of Rosenblath's cases, agrees in general with the points I made in my first report against the sarcomatous nature of the process, and emphasizes the clinical and anatomic reasons for assigning it to the group of leucemia and pseudoleucemia, and with the histologic structure of lymphosarcoma or lymphoma. But he prefers the term chloroma as less likely to involve error. According to him one could suppose the disease began in the prevertebral lymph glands, or perhaps in the lymphatic tissue of the bone-marrow. He also admitted the possibility, in his own case, of an origin in old, caseated, retroperitoneal glands. He thought the blood condition was not sufficiently known to place the disease in a definite group of leucemic processes.

Dunlop, too, thinks that lymphosarcoma is perhaps the best term to apply to "the growths found in chloroma resembling on the one hand lymphomas in their structures, and sarcomas in the fact that they arise from the periosteum and that they spread by metastasis." This is of course somewhat different from the conception of lymphosarcoma held by some of the authors previously quoted, and not altogether in line with recent views on the pathology of sarcoma.

Gümbel described the tumors in his cases as lymphomatous, having many resemblances to bone-marrow. The cells were mononuclear large lymphocytes, like those in the blood and bone-marrow, lying in the scanty connective tissue, evidently that of the original tissue. The tumor was not circumscribed in any part, but spread out irregularly, accordingly to the denseness of adjacent tissue. The tumors were poorly vascularized, without evidences of newly-formed vessels. Admitting the resemblance of the tumor to sarcoma, he points out that chloroma is essentially limited by mechanical conditions as regards its spread, unlike the unlimited growths of sarcoma. Another point is the impossibility of finding a primary growth. Other points of difference are: The absence of giant cells, of bone formations, of characteristic circumscribed metastases in internal organs. The cells of the tumor he, too, thinks are the same kind as the majority of those in the blood, the bone-marrow, and the splenic pulp. "All the lymphoid tissue in the body was increased. In the bone-marrow the normal elements were lessened or absent, but the large lymphocytes much increased." This led him to place the primary seat in the bone-marrow. Moreover, the tumors first demonstrable clinically and apparently the oldest anatomically, are with rare exceptions near the skeletal system —*i.e.*, in tissue nearly related to bone-marrow. He considered the tumors as secondary formations, beginning probably in lymphadenoid tissue and growing out from there. "Inasmuch as chloroma remains separated from the lymph glands by their capsules, it is evident that the change in the glands is the expression of the general disease, that the tumor does not originate in them. The term lymphosarcoma is therefore not applicable." He notes the close resemblance that chloroma cases have to acute leucemia in their respective terminal stages.

Trevithick rejected the idea of sarcoma on account of the symmetry of the lesions, the relative position of the organs invaded, the irregularly disorderly disposition of the individual invading cells, and the marked absence of vascularization. He described the cells in the various tissues and found them identical. The bodies are irregularly polygonal, the nuclei large. In the lymphatic glands he found many vascular, presumably lymphatic, spaces, wherein the endothelium is evidently undergoing immense hyperplasia. These he thought had an important part in the morbid condition.

Hichens, on the other hand, who has a somewhat imperfect idea of my own reasons for objecting to the term sarcoma, thinks that the erosion of bone which occurs in some cases is suggestive of sarcoma—which of course might be said quite as truly of aneurism of the aorta—and suggests that lymphatic leucemia is a fluid sarcoma of the hematopoietic system and that chloroma is only another manifestation of the same disease characterized by solid deposits.

Sternberg considered the process a lymphosarcomatosis in the sense of Kundrat and Paltauf. His patient probably died early in the disease, before the process had spread beyond the lymph glands. He thinks there are certain relations between pseudoleucemia, leucemia, and lymphosarcoma, though the anatomic separation is possible. To him the difference depends on the presence or absence of heterotopy. The growths in the dura and periosteum he considered evidence of lymphosarcoma rather than lymphoma.

Klein and Steinhaus were the first to report a marked departure in the histology of chloroma. In films spread from the spleen, bone-marrow, and the green tumors, they found that most of the cells instead of being lymphocytes were neutrophile cells, mostly myelocytes. The rest were lymphocytes, or in the bone-marrow, these with eosinophiles and red corpuscles. Sections showed the same kind of cells. Accordingly, these authors would remove chloroma from the lymphosarcoma group and place it among the leucemias. The green color they would give a subordinate place among the characteristics of chloroma, and would lay most stress upon the

localization, the great aggressiveness, the tendency to infiltration, and the rapid course.

Weinberger says that in his case the anatomic diagnosis of Weichselbaum was: Lymphatic leucemia, leucemic lymphoma, chloroma. He thought it differed from lymphosarcoma of Kundrat in that the lymphoid nodes, notwithstanding their extent, remain in the place of primary growth, and do not infiltrate the adjacent tissue. It resembles lymphatic leucemia in the nodular foci in the mucous membranes, the serosa, peritoneum, liver, spleen, and bone-marrow, and in the blood picture.

Türk objects to the separation of leucemia, and especially lymphatic leucemia, and lymphosarcoma, and insists on the occurrence of transition stages from one to the other. According to him, chloroma is a local lymphosarcoma, a malignant lymphoid hyperplasia, with or without lymphemia. He alludes to the intramuscular infiltration as an evidence of the malignant character of the disease. The differences in blood pictures can be explained by the affection of the bone-marrow.

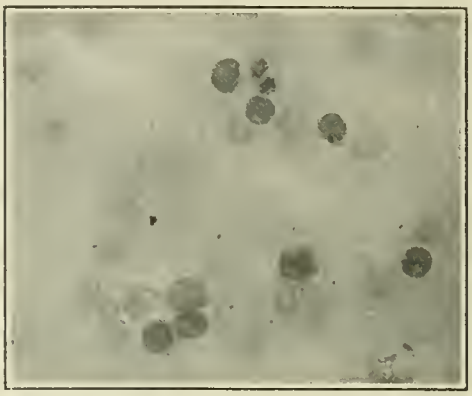
While there are some contradictions and differences of opinion regarding the growths among those who have examined cases of chloroma, I think it can be said that histologically most of them have a structure that can best be compared with that of the leucemic lymphomata. That certain variations occur, however, seems beyond question, and I believe that Dr. Warthin's examinations in this case reveal some important demonstrations of this fact.

MICROSCOPICAL EXAMINATION BY DR. WARTHIN.

Preparation. In the preparation of the material for microscopic examination alcohol, formalin, mercuric chloride, Zenker's, Müller's, and Flemming's were used as fixing and hardening agents. Some of the material was also examined in the fresh state. A portion was fixed and embedded in formol-agar. The greater part was embedded in paraffin. Celloidin embedding was used for a few tissues and for the material fixed in Flemming's. A great variety of staining methods was employed: hematoxylin and eosin, Van Gieson's, carbolthionin, Wright's, Romanowsky's, Jenner's, kresyl echt-violet, polychrome methylene blue, triacid, Weigert's fibrin, Weigert's yellow elastic, Mallory's reticulum, etc. Sudan III was used for fresh material and for sections cut in formol-agar. Potassium ferrocyanide and HCl were used for the iron test. Ebner's fluid was used for decalcifying the vertebræ.

Prevertebral Green Tissue.—Sections cut at right angles to the surface of the prevertebral green tissue show that the upper portion consists of adipose tissue and the lower portion of the dense connective tissue of the prevertebral fascia and periosteum, both being densely infiltrated with cells that in general correspond to the cells found in the blood as described above. The infiltration of the denser connective tissue is arranged in rows or cords of cells extending in the lymph spaces and blood vessels between the parallel to the dense fibers of the reticulum. In the adipose tissue the infiltration is more irregular and the cords of cells proceed in all directions between the fat cells. In many places the latter are atrophic or have entirely disappeared, their places being taken by masses of new cells. In the denser parts of the periosteum the cells are often

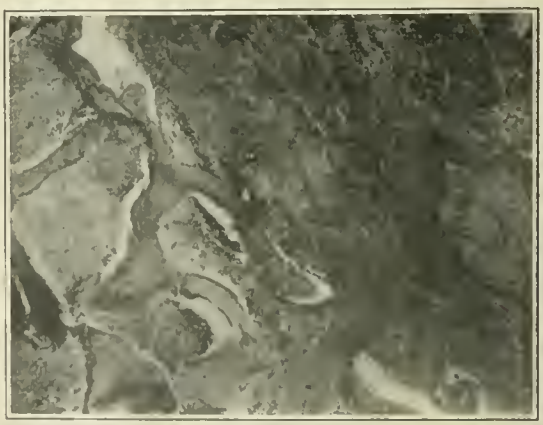
Fig. 1.



Blood showing differences in size, shape, and relative size of nucleus and amount of protoplasm in the lymphocytes.

arranged in rows of single file, and are elongated, often spindle-shaped. In the looser fat tissue and in the lymphatics and blood vessels the cells are usually round or oval. The majority of the nuclei are somewhat larger than a red blood cell, stain moderately deeply, or are pale and have a distinct, finely filamentous network of chromatin. In general the nuclei are round or elongated according to the situation in which they are found, but they are also frequently indented, saddle-bag shaped, bilobed, or divided completely into two. In the cells having two nuclei the latter are often somewhat smaller than the nucleus of the mononuclear forms, stain a little more deeply, and have coarser chromatin threads. The appearances sometimes suggest a recent mitotic division.

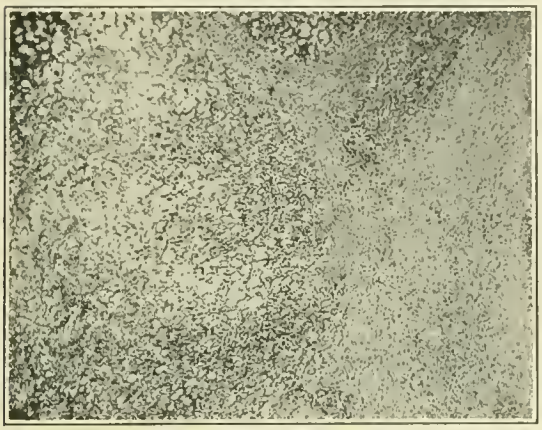
Fig. 2.



Vertebra periosteum and adjacent tissue.

The majority of the cells of the infiltration possess a small rim of protoplasm varying in thickness, and usually more prominent at one side of the cell. Other cells have a more abun-

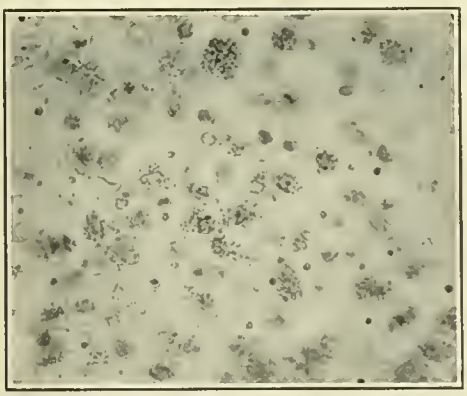
Fig. 3.



Prevertebral green tissue. Periosteum and fat infiltration.

dant protoplasm, but many show no protoplasmic rim at all. On the whole the proportion of cells showing a distinct protoplasmic body is greater in the infiltration than in the blood. The most striking feature of the infiltration is the fact that the majority of cells having a well-marked protoplasmic rim contain *eosinophile granules*. These granules for the greater part are in all respects

Fig. 4.



Primary growth showing large proportion of eosinophile cells. High power.

apparently identical with the granules of ordinary eosinophile cells; they are of the same size, possess the same staining reactions, and in unstained fresh sections appear as greenish-yellow, refractive granules. In some cells the eosinophile granules are fewer, smaller, and paler. A small proportion of cells have a neutrophile granulation, and a smaller number still have a distinct basophile granulation. Apparent transition forms between these are sometimes found. In those cells possessing no granulation the protoplasmic rim is either colorless or at times stains faintly with the nuclear stain, at other times with eosin. Apparent transition forms are seen between the cells without granulation and those with numerous eosinophile granules.

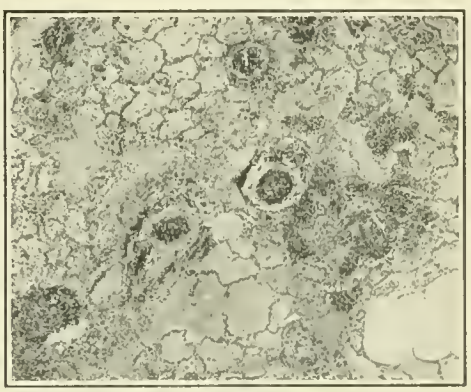
In the majority of fields the number of the numerous eosinophiles is so great that a red tint is given to the section. In some fields every cell may show eosinophile granulation; few fields exist without some eosinophile cells, while in the great majority of fields the proportion of eosinophile cells by actual count runs from 50 to 75 per cent. While from the numerous transition forms found everywhere there can be no doubt

Fig. 5.

Metastases in kidney.

that the eosinophile cells are derived from the large "lymphocytes" of the infiltration, it is impossible to distinguish those eosinophile cells having an abundant protoplasm from the eosinophile myelocyte. Few polymorphonuclear eosinophiles are found in the infiltration. In the denser portions of the periosteum the number of eosinphiles is not so great as in the looser connective tissue and adipose tissue. Many of the spindle-shaped cells in the former, however, show eosinophile

Fig. 6.



Metastases in lung. Pulmonary vessel filled with atypical lymphocytes.

granules. On the whole, the eosinophile cells show no special grouping with reference to the blood vessels.

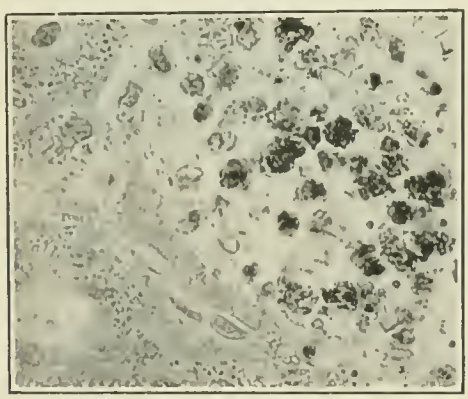
Mast-cells are few or entirely absent. Few polymorphonuclear leucocytes are seen, and are

easily distinguished by their more deeply staining nuclei. Some of these are also eosinophilous. Typical small lymphocytes are also rare. No giant cells or phagocytes found. Few mitoses seen (this may be accounted for by the long time elapsing between death and autopsy), although numerous appearances suggest clumped mitoses. The transition forms of indentation, constriction, and complete division of the nucleus suggest amitotic division. Mitoses were twice seen in cells with eosinophile granulation.

Evidences of degeneration of individual cells are present in the form of pycnosis and karyorrhexis, but definite areas or centers of degeneration are not seen. A few cells containing small vacuoles were found.

No pigment granules are present in any of the cells of the infiltration. The iron test was negative in so far as these cells were concerned. The treatment with osmic acid was also negative. The staining of fresh sections with Sudan III

Fig. 7.



Small metastasis in liver, showing many eosinophile cells. High power.

showed fat droplets in the cells of the reticulum, but not in those of the infiltration. In some areas a very slight diffuse orange was imparted to the cell protoplasm. In the fresh sections the eosinophile granules were seen distinctly as refractive, shining granules having a distinct greenish-yellow color. No other evidence as to the source of the green color of the tissue could be obtained.

There are no positive evidences of the formation of new blood vessels in the infiltrated tissues. On the other hand, these appear poorly vascularized, the blood vessels being apparently those of the original tissue and more or less filled with cells of the same type as those of the infiltration. Very few red cells are seen in the vessels. Under the high power red blood cells may be seen in small numbers scattered throughout the reticular spaces in company with the new cells. It is difficult to decide whether these represent small hemorrhages or whether the red cells lie in blood vessels which are more or less obturated by the new cells. Evidences of red-cell destruction are present in some places, the red cells lying in association with the new cells showing fragmentation, or are represented by granules of iron-containing pigment. As mentioned above, no red cells or blood pigment of any kind occur within the cells of the infiltration. The reticulum of the infiltration is chiefly or wholly that of the original tissues, but there is undoubtedly some increase of reticulum both in the periosteum and denser fascia as well as in the adipose tissue. There is also some thickening of the walls of the medium and larger-sized blood vessels, and an endothelial proliferation of the smaller. As a rule the walls of the large vessels show but little or no infiltration by the new cells.

The infiltration behaves in all respects as a *tumor infiltration*. The original tissues are either crowded apart, compressed, or have become atrophic. Such changes are seen particularly in the case of nerve trunks and ganglia. The spinal nerves and ganglia show especially the results of such infiltration and compression. In the case of ganglia that are completely surrounded by the infiltration and ganglion cells are atrophic and present various appearances of degeneration. The nerve trunks show an infiltration along the blood vessels and lymphatics.

The general picture presented microscopically by sections of the prevertebral green tissue is that of a *tumor infiltration in which the cells are of the type of large lymphocytes or myelocytes, the majority showing eosinophile granulation.*

Smears of the Prevertebral Green Tissue.—Smears stained with hematoxylin and eosin, Wright's method, and the triacid show that the cells are chiefly of the "large lymphocyte" type as found in the blood of this case. The majority have no protoplasmic rim. Many show eosinophile granulation. Clumped and fragmented forms are numerous and many of the nuclei are vacuolated. Few red blood cells are found in the smears.

Green Tissue from Sternum.—The microscopical study of this shows precisely the same structure and character of infiltration of the periosteum and overlying fat and connective tissues as in the case of the prevertebral green tissue. If there is any difference the number of eosinophiles is greater. Smears from this tissue show the same "large lymphocyte" type of cell, the majority eosinophilous.

Bone-Marrow.—Sections of the sternal marrow show that the normal marrow elements are almost wholly replaced by cells of the same type as those of the periosteal infiltration—that is, by cells of the large lymphocyte type, the majority showing eosinophile granulation. No bone-marrow giant cells are seen. Very few red blood cells are present and only two cells were found that could be regarded as nucleated red cells. Few neutrophile myelocytes are present and small lymphocytes and polymorphonuclears are also very few in number. Transition forms between the large lymphocytes with small protoplasmic rim and those with more abundant protoplasm containing eosinophile granules are numerous.

Inasmuch as the eosinophile "large lymphocyte" passes by transition forms into cells morphologically identical with eosinophile myelocytes, this fact may be taken as evidence of the derivation of the latter type of cell from the former. The eosinophiles are somewhat unevenly distributed; in some fields 50 to 80 per cent. of all nucleated cells may show eosinophile granulation, in others the proportion may drop to 10 to 20 per cent., but in many sections the majority of fields show a preponderance of eosinophiles. The polymorphonuclear eosinophiles are relatively very few. The nuclei of the majority of the eosinophiles in general resemble those of the non-eosinophile large lymphocytes. All possible transition forms exist between such eosinophiles and those forms with more abundant protoplasm resembling eosinophile myelocytes. In their general characteristics, size, shape, pale nuclei, small amount of protoplasm, etc., the cells constituting the mass of the sternal marrow are identical with those of the periosteal infiltration. The capillaries and blood vessels of the marrow are nearly completely obturated by cords and masses of cells of the same type. The delicate reticulum of the marrow appears to be but slightly increased.

Smears of Sternal Marrow.—Smears of the sternal marrow fixed in absolute alcohol and ether and stained with hematoxylin and eosin, triacid, etc., or fixed and stained by Wright's method are composed almost wholly of cells of the "large lymphocyte" type, the majority containing eosinophile granules. Numerous large eosinophile cells with very pale, large, single nuclei are also present. These resemble eosinophile myelocytes; many of the nuclei are vacuolated. There is a great variation in the size of the eosinophiles, and numerous transition forms exist. The majority of the non-eosinophiles have little or no protoplasmic rim and correspond with the cells found in the periosteal infiltration and in the blood vessels. The nuclei of these also show vacuoles of varying size. Numerous degeneration forms are present. The smears contain but a few red blood cells and only a very few nucleated reds. The background of the smears is made up to a very large extent of free eosinophile granules.

Vertebral Marrow.—Sections of decalcified portions of the bodies of the vertebræ show an enlargement of the marrow spaces and a rarefaction of the bony trabeculæ. The enlarged marrow spaces are filled with closely crowded cells of the "large lymphocyte" type identical with those found in the sternal marrow, prevertebral and sternal periosteal infiltrations, and in the blood vessels. The number of cells having a rim of protoplasm is somewhat greater than elsewhere, and many cells show a distinct cell body. There are also more degenerating forms. The eosinophile cells are not quite so numerous as in the sternal marrow or the periosteal infiltrations, but nevertheless in the majorty of fields form a relatively high proportion of all cells present. In the portions fixed in Müller's fluid the protoplasm of the majority of the cells replacing the marrow elements is distinctly chromaffinic to some extent, having a distinct brownish or greenish-yellow color. There are but few red cells and no nucleated red cells were found. The polymorphonuclears and small lymphocytes are relatively very rare. No bone-marrow giant cells were seen and no plasma or mast-cells found. Owing to the fixation used the neutrophile cells could not be distinguished. In some of the large lymphocyte forms having an abundant protoplasm, very small and light eosinophile granules are present. The reticulum of the marrow is apparently slightly increased and consists of fine fibrillæ.

The most important fact determined in regard to the relationship between the marrow condition and the prevertebral infiltration is the demonstration of the direct connection existing between the two. Sections made through the prevertebral green tissue and periosteum, and extending into the body of the vertebra show that the large masses of cells in the enlarged marrow spaces are in many instances directly continuous with the periosteal infiltration by means of relatively large openings in the bone. Smaller cords of cells extend from the marrow spaces through small openings in the bone and are continuous without break with the periosteal infiltration. Such direct continuity between the marrow spaces and the periosteal infiltration are so numerous that they can be seen in nearly every section. The openings are most probably enlarged lymphatics or blood vessels. Red cells occur in some of them in association with the cells of the large lymphocyte type. In other cases the growth of cells in the medullary spaces appear to have caused a disappearance of bone and a direct extension of cell growth outward into the prevertebral tissues. The infiltration from the vertebræ does not extend into the intervertebral disks and is scanty over them. It surrounds the body of the vertebra more or less uniformly, but is most marked at those places where it is continuous with the growth in the marrow spaces. In some places masses of cells have grown or collected beneath the periosteum, raising it from the bone. The various pictures presented suggest growth outward from the bone and not from without into it. The spinal nerves and ganglia are surrounded by the infiltration and are to some extent themselves infiltrated. There is an increase of interstitial connective tissue within some of the ganglia.

The careful study of such sections leads to the conviction that we have to deal here with a *primary growth within the marrow spaces which infiltrates or grows directly through the lymphatics and blood vessels or breaks through the bone and secondarily involves the periosteum and surrounding tissues.* The cells of this growth are identical morphologically with the so-called large "lymphocytes," large mononuclears, and eosinophile myelocytes of the normal bone-marrow.

Smears of Vertebral Marrow.—Smears of the

vertebral marrow fixed in absolute alcohol and ether and stained with hematoxylin and eosin, triacid, etc., or fixed and stained with Wright's, present the same picture of those obtained from the sternal marrow. Few red cells are present, and no nucleated forms were found. The number of eosinophiles appears not so great, and there is a larger proportion of degenerating forms. The majority of the nuclei have either large or small vacuoles, many nuclei consisting of a large vacuole having only a faint rim of chromatin. Numerous nuclear forms suggesting clumped mitoses are present as well as those forms suggesting amitotic division. The background of the smears is made up chiefly of eosinophile granules. Numerous very pale nuclei covered with eosinophile granules and having no protoplasmic body are seen.

(To be Continued.)

MEDICAL PROGRESS.

MEDICINE.

Ainhum.—H. N. Blum (*Med. Record,* October 22, 1904) reviews what is known concerning this peculiar disease, and cites a series of typical cases from the literature. The affection occurs almost always amongst the dark-skinned races of tropical and subtropical regions, and is characterized by a progressive constricting sclerotic ring around the bases of the digits of the hand or foot, especially selecting the little toe of either or both feet and ending in a gradual amputation of that portion of the affected member distal to the constriction. The condition is local, there being no manifestations except on the toes or fingers, and it never recurs at the site of amputation. It is sometimes confused with leprosy or Raynaud's disease, but may be differentiated from these by its duration, its purely local nature, the characteristic "scleroderma" and the absence of the specific bacilli of leprosy. Very little is known as to its cause, and the author agrees with Matas in terming it a trophoneurosis. His own case occurred in a negress of sixty-five years, whose right little toe was affected in the characteristic way. The toe was disarticulated at the metatarsophalangeal joint under cocaine anesthesia, and the cicatrix has since remained in healthy condition.

Rhythmical Mechanical Compression of the Thorax in the Treatment of Dyspnea.—Various drugs and also mechanical or manual compression have been used for the treatment of conditions in which the chest does not perform proper excursions, but none, according to D. Boghean (*Berl. klin. Woch.,* October 17, 1904) have been entirely successful. Any form of apparatus with which it is desired to deepen the respirations, must neither wear out the patience nor the strength of the patient or operator, and in order to be regular and constant in its action, must be kept in motion by a suitable motor and easily regulated. The author has devised a rather complicated apparatus which is believed to fulfil these requirements. It is driven by a small electric motor and the active principle consists of a pair of pads which compress the patient's chest, after the machine is set in motion, during the act of expiration, so that a greater volume of air is expressed from the person's lungs than would occur with his unaided efforts. This is believed to increase the carbon dioxide output and thus relieve the subjective sense of dyspnea. The question as to whether it is the lack of oxygen or the accumulation of carbon dioxide which causes the dyspnea in any given case is answered by the observations of a host of writers who claim that both are at fault, but that the organism is much more tolerant toward a lack of oxygen than toward an excess of carbon dioxide.

Osteomalacia and Thyroid Disease.—The not uncommon association of osteomalacia with disease of the thyroid gland—myxedema, tetanus, and especially Basedow's disease,—have led to a series of observations by E. Hönicke (*Berl. klin. Woch.,* October 31, 1904) which seems to show that osteomalacia may be traced to a primary disease of the thyroid. He has studied the geographical distribution carefully of both diseases and has also noted that the thyroid gland in osteomalacia was abnormal and that in the latter condition, symptoms of thyroid disease were also present. It is probable that a primary disease of the thyroid glands leads to a disturbance of the phosphorus metabolism, which is the main characteristic of osteomalacia. The various forms of the latter constitute a disease entity, and the peculiarities of the puerperal form may be explained on physiological grounds. The operation of castration is effectual because it diminishes the loss of phosphorus, and the administration of phosphorus is of value because it increases the amount of phosphorus. The author is about to publish a more complete account of his observations of which this is merely a preliminary communication.

Artificial Pernicious Anemia.—By repeated injections of pyrogallic acid into animals, grave blood-changes may be brought about which in many ways resembles pernicious anemia. In a series of experiments, P. Reckzeh (*Zeitsch. f. klin. Med.,* Vol. 54, Nos. 3 and 4) found marked reduction of hemoglobin and red cells, poikilocytosis and the appearance of nucleated erythroblasts. An advanced degree of anemia is, however, necessary for the appearance of megaloblasts. If an examination of the bone-marrow be made, changes typical for pernicious anemia may also be found. A marked leucocytosis is also a pronounced symptom; at first the polymorphonuclear elements, especially the younger forms with single, indented nucleus predominate, later, the lymphocytes are decidedly more abundant, indicating general failure on part of the bone-marrow. All these changes correspond to observations made on the blood of cases of pernicious anemia in man. Strangely enough, if young animals are selected for experiment, the composition of the blood resembles that of the anemia pseudoleucemia infantum of v. Jaksch in that the leucocytes are enormously increased and the relation of whites to reds frequently reaches 1 to 12. It is probable, therefore, that this disease is closely allied to pernicious anemia and the leucocytes are more numerous solely because the bone-marrow of the young reacts more strongly to irritation. This is corroborated by the observation that the polymorphonuclear cells predominate.

Gastric and Intestinal Crisis.—In all cases of gastric and intestinal crisis of tabetic origin observed by C. A. Ewald (*Centralbl. f. d. gesamt. Therapie,* October, 1904), other symptoms of tabes were also present. Common eye symptoms were pupillary rigidity, paralysis of the external muscles of the eye and optic atrophy. Difference in the size of the two pupils is not so valuable since it may occur in other conditions and even in health. It must not be forgotten that pupillary rigidity may also be an early symptom of multiple sclerosis, cerebral syphilis or tumor, general paresis and even alcoholic neuritis. It is, therefore, wrong to diagnose tabes from only one or two symptoms. Westphal's sign

is of great importance, but it has been known to disappear and then to reappear in the later stages. Disturbances of sensation, especially about the lower extremities, are only rarely absent and sometimes paresthesiæ in the posterior pharyngeal wall on the anal mucous membrane are complained of. In the cases observed by the author, a history of syphilis was obtained in 62 per cent. The average duration of the disease was two years and ten months. A period of a year and a half may lie between the first attacks, but later they increase in frequency and may appear daily. The duration of each separate attack varies between one-half to forty-eight hours. Their onset is very sudden with epigastric cramps and nausea, soon followed by severe and extremely painful emesis. An aura in the form of pain in chest and back is sometimes observed. As soon as other tabetic symptoms make their appearance, the crises usually lose their intensity. The condition of the gastric juice varies, but diminished acidity seems to be the rule. Constipation is not rarely present. Rectal crises manifest themselves in intense tenesmus with the discharge of only slight amounts of feces and mucus. They are less frequent and never occur together with gastric crisis. The treatment is very unsatisfactory and morphine can hardly be dispensed with, since there is as yet no specific. Recently, epidural injections of cocaine have been employed with good result.

THERAPEUTICS.

Treatment of Laryngeal Tuberculosis.—Laryngeal tuberculosis without its pulmonary congener is very rare, and in cases where examination of the lungs fails to elicit the symptoms of pulmonary invasion Nikitin (*Prakt. Vrach,* No. 39, 1904) thinks that the changes in the lungs are so deep-seated and limited as to escape for the time being objective examination. The results of the treatment as based on observations of 1,732 cases, are never permanent, but a temporary benefit is undoubted. Thus in one case of infiltration of the arytenoid cartilage the author succeeded in bringing about cicatrization of the ulcer with subsequent complete cure of the patient; who seven months later, however, died of tuberculous meningitis. In another case treatment of the larynx by curettage followed by the application of lactic acid and general constitutional treatment has so far improved the patient's condition that he was enabled to resume and contiue his avocation, that of a teacher, for two years; he succumbed, however, to pulmonary tuberculosis, although he never complained of laryngeal trouble again. The treatment is either medicinal or surgical. The medicinal means are either antiseptic or analgesic. In hypersensitive patients the treatment should be limited to inhalation or insufflation of solutions or powders. The author finds an excellent palliative in one-half per cent. solution of nirvanin followed by the insufflation of orthoform or di-iodoform. If the infiltration is limited and the course of the pulmonary affection slow, curettage may be resorted to, to be followed by the application of lactic acid. Laryngeal ulcers are to be treated by inunction with solutions of lactic acid, phenol-glycerin, parachlorphenol or phenosalyl. The more superficial the ulcers the easier they admit of application. Phenol, when dissolved in glycerin, yields completely its burning quality and may therefore be applied in concentrated solutions. A transient stage between the medical and surgical treatment is to be seen in the application of galvanocaustics and electrolysis. Tracheotomy as recommended once by M. Schmidt, was at first received favorably, but it was gradually pushed into the background, for to be successful it must be employed early in the disease, when the patients rather prefer milder treatment. Moreover, tracheotomy is objectionable on the ground of constant irritation as induced by the presence of the canula, the possible risk of necrosis of the tissues, the predisposition to infection, and the difficulty which is presented to the expulsion of the pulmonary secretion. More is to be hoped from tracheotomy in conjunction with curettement of the tuberculous infiltrations by the aid of a sharp spoon, in cases that are not very far advanced. The operation enables one to do the curettage in an open field, and not through the mouth, which presents considerable difficulties. Thus in a girl, aged nineteen years, a laryngotomy was performed after a preliminary tracheotomy, and after opening the larynx the infiltration on the posterior wall of the larynx and ulcers on the left vocal cord were curetted and then treated by galvanocautery. The laryngeal wound was then closed. The pain on deglutition was gradually diminished, and on the sixth day when the canula was taken out, patient was able to swallow freely. The postoperative course ran smoothly. Later, she completely recovered, but the voice remained hoarse, and examination of the larynx elicited the presence of cicatrices at the sites of the ulcers. At present, at the expiration of two years, patient still enjoys excellent health.

Treatment of Leucemia with Roentgen Rays.—One case of myelogenous leucemia was treated daily by the Roentgen rays for one month by D. Fried (*Münch. med. Woch.,* October 4, 1904). The daily exposure was three to fifteen minutes. At the end of the treatment, the leucocytes had fallen from 62,000 to 6,000, the spleen was considerably smaller, the patient's weight had increased and subjective symptoms were no longer complained of. His improvement still persisted a month and a half later. Similar good results were observed in a second case. It has been proven by animal experiments that cells of the spleen and lymph-nodes are readily absorbed under the influence of the Roentgen rays and early cases of leucemia are entirely benefited more than by anything else. It is still too early to say if the improvement is permanent or if advanced cases are also influenced.

Sprain and its Treatment.—G. Norstrom warmly advocates (*Med. Rec.,* November 19, 1904) early massage and active and passive motion in cases of sprain. If physicians paid more attention to this method of treatment they would keep many patients out of the hands of "bone setters" and other quacks. Properly applied massage often cures in one or two cases that under the old treatment by immobilization would consume weeks. The massage first applied should be very gentle, so as not to cause irritation or too much pain, and then gradually be increased as the tension of the tissues subsides. Not until the inflammation has become less intense is it advisable to introduce real frictions. At first the sittings should be protracted, of at least twenty minutes' duration, and should, when possible, be repeated several times a day. The treatment may be summed up as follows: (1) At the initial stage, in the presence of classical phenomena, including a great deal of pain, effleurage. (2) When the pain has decreased a great deal frictions and passive movements; later, active movements. Walking at the beginning ought not to be permitted. (3) In all sprains of the lower

extremities, after every seance, application of a gauze bandage, a precaution all the more indicated when the patients are allowed to use their legs and walk. (4) In order to prevent real relapses, as well as to prevent the inflammation taking on a chronic character, the treatment ought to be kept up until complete restitution has taken place.

Oxygen in Combination with the Different General Anesthetics.—J. T. Gwathmey publishes (*Med. Rec.*, November 19, 1904) the results of an extensive series of observations made to determine the value of oxygen as an addition to general anesthetics. The conclusion reached is that oxygen increases the value of anesthetics as regards life, without decreasing their anesthetic effect. The author's investigations were made upon a series of one hundred cats, chosen so as to present as little variation in size, etc., as possible. The animals were killed by means of the various anesthetics in common use, administered by means of a closed mask and with the admixture or either air or oxygen, the time required being noted in each case. As a result of the figures so obtained the author says that, regardless of the anesthetic used, animals have lived twice as long with oxygen as when air was used. They usually die quietly with oxygen, and in convulsions with air. With oxygen the heart also continued to beat longer after respiration ceased. Efforts at resuscitation are more likely to be successful when oxygen has been used, and in private practice the after-effects of the anesthetic are reduced by this means. The experiments show that a mixture of chloroform and oxygen is more than twice as safe as chloroform and air, and is also safer than any of the other general anesthetics with air. This means that instead of having a very high mortality, chloroform given with oxygen is now as safe as ether. But all of the other general anesthetics are also increased in value by oxygen, and the use of this method of administration practically eliminates the percentage of danger which has hitherto been recognized as inseparable from the practice of anesthesia.

Thiocol and Sirolin.—Very good results are reported by D. Szaboky (*Wien. klin. therap. Woch.*, October 16, 1904) from the use of thiocol and sirolin (a solution of thiocol). The former drug is given in doses of 0.5 gram four times daily, and incipient cases of tuberculosis are often cured or considerably benefited in four to six weeks. Even in advanced cases the cough is alleviated, the temperature reaches normal, and the appetite improves remarkably. In intestinal tuberculosis, thiocol has a very good effect, since it seems to be possessed of almost specific action upon the intestines. In laryngeal tuberculosis it may be applied locally with good result.

PRESCRIPTION HINTS.

Treatment of Pruritus Ani.—At the recent meeting of the British Medical Association Dr. Malcom Morris spoke on this subject. Pruritus ani, he said, is often very refractory to treatment, but the practitioner should never despair, as few cases are incurable, though many will tax his therapeutic ingenuity to the uttermost limit. The first thing to be done is to seek for the cause, and remove it or neutralize its action. Each group of cases—that is to say, those dependent on constitutional disorders, those produced by reflex disturbances, those due to a local condition, and those that are the expression of a neurosis—must be dealt with by measures appropriate to the causation. There are certain principles of therapeusis applicable to each of these several groups; but in the details of treatment each case must be dealt with in accordance with its special features and with the idiosyncrasy of the patient. In all cases, therefore, a careful examination, general and local, must be made before any system of treatment is instituted. The following formulæ have proved useful in his hands:

℞ Acid. carbolici ..... ℥xx
Cocaine hydrochlorat. ..... gr. x
Vaselin ..... ʒ j
Fiat ung.

℞ Acid carbol. ..... ʒ ss
Cocainæ ..... ʒ ss
Aq. laurocerasi ..... ʒ j
Aq. Rosæ ..... ʒ iij
Fiat Lot.

℞ Acid. carbol. ..... ʒ ss
Hyd. perchlor. ..... gr. ij
Ol. olivæ ..... ʒ ij
Ung. zinci oxid. benzoat. ..... ad. ʒ j
Fiat ung.

Tarry preparations are useful. The sapo carbonis detergens may be used for ablutions; the lotio picis carbonis may be employed in calamine lotion as a vehicle (ʒ ij of the former to ʒ viij of the latter). Tar, combined with bismuth, may also be applied in the form of an ointment, composed as follows:

℞ Ung. piois liquidæ ..... ʒ j
Bismuth subnitratis ..... gr. xx
Adipis ..... ad ʒ j
Fiat ung.

Compresses soaked in oil of cade are often very useful. Peruvian balsam in vaselin is a good application. A suppository of extract of belladonna (½ gr.) at bed-time, will often prevent the nocturnal exacerbation. Painting the part with lead in spirit and water is a soothing remedy. Nitrate of silver in sweet spirits of nitre (gr. iij to ʒ j) is often useful. Among other sedative remedies which may be tried are menthol, ichthyol, chloral hydrate, borax, benzoin, and tincture of iodine. When piles are the cause of the trouble, the unguentum gallae will often relieve the itching as well; painting or injecting with hamamelis is also useful for the same purpose. Oxide of zinc is best applied in the form of a cream as follows:

℞ Zinci oxidi ..... ʒ ij
Lanolini ..... ʒ ij
Ol. olivæ ..... ʒ ss
Aquæ calcis ..... ʒ ss

Among antiseptics, the most useful is mercury. A very convenient form is the oleate, which may advantageously be combined with oleate of morphine. An ointment composed of calomel ʒ ss to an ounce of vaseline is also serviceable. Black wash is particularly useful; it may be used either alone or in a vehicle of mucilage or tragacanth as follows: :

℞ Lot. nigræ } ..... ãā ʒ iv
Liq. calcis }
Mucilag. tragacanth ..... ʒ j

Another useful mercurial lotion is the following:

℞ Hyd. perchloridi ..... gr. ij
Glycerini ..... ʒ ss
Aq. chlorof. ad ..... ʒ iij

Ammoniated mercury in benzoated lard (gr. xx. ad ʒ j) is also valuable. Calomel in powder may render excellent service.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, DECEMBER 3, 1904.

FOOD PRESERVATIVES AND ADULTERANTS.

At the last meeting of the New York Academy of Medicine, Dr. H. W. Wiley, the Chief of the Bureau of Chemistry of the United States Department of Agriculture, read a preliminary report with regard to the influence of preservatives and adulterants in food upon the public health. A very full abstract of his interesting paper will be found in our Society Proceedings for this week. The full report, consisting of over 500 pages of printed matter, is to appear shortly.

The most interesting feature of the report is the thoroughgoing conservatism with which the subject has been approached and the judicial straightforwardness with which the conclusions are presented. Nothing is said that would give material for a scare head or a sensational news item, and accodingly, Dr. Wiley's report did not occupy the attention of the daily papers in any large degree. What has been lost in sensation, however, has been gained in scientific value, and there is no doubt that as Americans we may feel proud of the fact that the government investigations have been conducted in a manner so worthy of American science.

That even such mild preservatives as boric acid and borax may be a source of some danger, when constantly used in food, there can no longer be any doubt. The American investigators, however, did not find any of the serious effects that were claimed to have been observed in Germany. The various boric derivatives cause distinct disturbance of metabolism, a lessening of nitrogenous waste and an increase in the phosphate elimination. These are of themselves quite sufficient to deter those who are at all anxious about their health from the frequent use of food containing such preservatives. One effect always produced is a lessening in the weight of those who have partaken of these materials, either in large quantities for a short time, or in small quantities for a longer period. As a matter of fact, as was pointed out in the discussion, boric acid has long been recognized by conservative clinicians as one of their best remedies for adiposity.

The only serious danger seems to be from the possibility of kidney irritation. There is no doubt that nephritis is on the increase in this as well as the boric acid taken with food is excreted through in most other civilized countries. Four-fifths of the kidneys. The remaining fifth is eliminated by the sweat glands, and thus grows a burdensome duty upon portions of the excretory system which are the best auxiliaries to the kidneys. There is no doubt, however, that other preservatives, such as saltpeter, are much more irritant to the kidneys, and yet have been used in the making of brine for many years, apparently without producing any serious effect and certainly without arousing exaggerated fears of possible evil results.

The whole subject deserves the conservative treatment it received at the hands of the Department of Agriculture and the only suggestion is not that the use of such preservatives should be forbidden by law, but that whenever their presence is considered necessary a label should be affixed to the food materials to indicate that fact. We have had much of sensational newspaperism with regard to this whole subject. It is refreshing to find it treated so calmly and judiciously, and at the same time so thoroughly and with such scientific completeness.

CEREBROSPINAL CYTODIAGNOSIS.

While cytodiagnosis, so far as the examination of pleural exudates is concerned, has now a well-established basis, and constitutes one of our most valuable diagnostic methods, the same

can hardly be maintained in the case of the cerebrospinal fluid. When it was shown at first that tuberculosis of the pleura, and this only, led to lymphocytosis of the corresponding exudate, it was thought that meningeal tuberculosis would give rise to a similarly specific result. As a matter of fact, evidence was soon forthcoming that tuberculous meningitis, in contradistinction to the ordinary form, was associated with an increased number of lymphocytes in the cerebrospinal fluid, but further investigation showed that this symptom could in no sense be regarded as specific. For, on the one hand, cases of meningeal tuberculosis were reported in which polynuclear neutrophiles predominated, while on the other lymphocytosis was observed in many non-tuberculous cases. It was thus found quite frequently in progressive paralysis and tabes, in cerebrospinal lues, in syphilitic hemiplegia, as also in uremia and tetanus, and still other conditions.

The explanation of this more generalized occurrence of lymphoctyosis in the cerebrospinal fluid was sought in the element of a supposed meningeal irritation. It is to be noted, however, that in cases of apoplexy of non-syphilitic origin (which the Germans very appropriately term "Alters Apoplexie") no lymphocytosis occurs, even though most marked symptoms of irritation exist. In syphilitic hemiplegia, on the other hand, an increased number of lymphocytes is apparently constant. The conclusion therefore would seem quite justifiable that the syphilis and not the hemiplegia is the deciding factor in the production of the lymphocytosis.

Niedner and Mamlock, in a recent communication from v. Leyden's clinic, have published a series of observations which tend to throw new light upon this question. They point out that the lymphocytosis, which is observed not only in syphilitic cerebrospinal affections, but in syphilis in general apparently, as also in uremia and tetanus, suggests that intoxications may play a prominent rôle in its production, especially if a virus should be operative which is constantly present or renewed, and which produces a continuous irritation of the central nervous system. This assumption would also explain the absence of lymphocytosis in epilepsy which, barring Merzbacher's statement to the contrary, appears to be the rule. Experiments on rabbits, in which convulsions were produced by means of strychnine, lend support to this view.

That an intoxication in itself, however, is not necessary, and that the time element is even more important is shown by the observation that lymphocytosis may also occur in certain cases of brain tumor, and Niedner and Mamlock suggest that in the traumatic cases of epilepsy reported by Merzbacher, in which the lymphocytes were found increased, the result was probably referable to prolonged and intense stimulation. Experiments in this direction likewise yielded positive results. Meningeal irritation, accordingly, if of any moment at all in the production of lymphocytosis, can only be regarded as a factor of secondary importance.

Viewed from the standpoint of diagnosis, the examination of the cerebrospinal fluid thus appears somewhat disappointing in its general aspects. That it may furnish information of value, however, is undoubted. Further investigations are now urgently needed to ascertain the earliest period of syphilis at which lymphocytosis will occur, and to determine the phases of the disease with which it is associated. That it may be demonstrable at a time when secondary symptoms already exist (ulcus durum and exanthem) appears certain.

ECHOES AND NEWS.

NEW YORK.

Dr. Sachs Leaves the Polyclinic.—Dr. B. Sachs has resigned his position as Professor of Neurology in the New York Polyclinic Medical School.

Eastern Medical Society.—At the annual meeting of the Eastern Medical Society, to be held at Clinton Hall, December 9, an address will be delivered by Dr. A. Jacobi. The Genito-Urinary Section of the Eastern Medical Society will meet on Tuesday, December 6, at 8.30 P.M., at Clinton Hall, 151-153 Clinton Street, Manhattan. Program: Five-minute papers on "Syphilis, as Observed in General Practice." (1) Syphilis of the Nose and Throat, by I. Grushlaw, M.D.; (2) Syphilis of the Eye, by A. A. Himowich, M.D.; (3) Syphilis in Obstetrics and Gynecology, by E. K. Browd, M.D.; (4) Syphilis of the Nervous System, by Emil Altman, M.D.; (5) Syphilis of the Viscera, by L. F. W. Haas, M.D.; (6) Syphilis in Surgery, by Chas. Goodman, M.D.; (7) Syphilis in Pediatrics, by A. Hymanson, M.D.; (8) Pathology and Diagnosis of Syphilis, by Ludwig Weiss, M.D.; (9) Treatment of Syphilis, by Daniel A. Sinclair, M.D. Discussion by Drs. S. Lustgarten, Charles Warrenne Allen, Samuel W. Brickner and B Lapowski. The profession is invited.

Annual Meeting of Skin and Cancer Hospital.—The following officers were elected at the twenty-second annual meeting of the New York Skin and Cancer Hospital at Nineteenth Street and Second Avenue: President, J. Cleveland Cady; Vice-President, William C. Witter; Secretary, L. Duncan Bulkley; Treasurer, Edward Winslow. The hospital has administered during the past year to some five thousand patients.

Health Board Dairy Inspection.—The plan suggested by James P. Atkinson, chemist of the Health Department, seeking to get at the root of the adulteration evil, provides that no permit shall be given to any concern to sell milk in the city unless the right to inspect the dairies of the concern is conceded as a condition. If at any time the dairies are found not to meet the requirements of cleanliness made by the Board of Health the permit to sell milk in the city shall, according to the plan suggested, be revoked at the discretion of the Board. Local inspection is at present fairly well systematized, each milk store being listed and the city divided into districts, so that the inspectors can keep close watch upon the retailers. Many arrests in all parts of the city show that adulterated milk is being sold without regard to locality. Raids have been made on some of the largest retail stores and depots and samples of milk taken which failed to pass satisfactorily through rigid chemical tests. Retailers who supply some of the largest hotels and restaurants have been found to have in their possession milk as far from pure as some of the samples taken from dealers in the east side tenement house districts. Manhattan has been divided into eight districts for inspection. There are three districts on the west side and five on the east side. There are 5,137 milk stores in Manhattan, and the inspectors from the Health Department make the rounds of them by districts from day to day. The large number of arrests recently after adulterated milk had been found in possession of the retailers, has caused the retailers to be more exacting with the wholesale dealers, and so far as this affects the quality of the general supply the results have been gratifying. It is almost invariably asserted by the accused retail dealer that the milk was adulterated before it was sold to him. A great advance will have been made if inspection of the dairies be made a routine procedure.

PHILADELPHIA.

The Pathological Society of Philadelphia.—Dr. Victor C. Vaughan, of the University of Michigan, will address the Philadelphia Pathological Society on December 8, at the College of Physicians, on the relation of Food Adulteration to the Public Health. A reception will be tendered to Dr. Vaughan immediately after the meeting.

Exhibit of White Haven Sanatorium.—Donation day for the White Haven Sanatorium was held during the past week at 1604 Chestnut Street, where an exhibition was given of the work of the institution. Model rooms for consumptives and tents for outdoor treatment were shown. Lectures by members of the Phipps Institute were given daily.

German Hospital.—Donation day at the German Hospital on Thanksgiving day was so well attended that over $12,500 were received, including $5,000 for a free bed. Improvements made during the past year include a four-story building containing a nurses' dormitory and diet kitchen at a cost of $30,000.

Infirmary and Laboratory at the Zoo.—A fully equipped infirmary and pathological laboratory has been established at the Philadelphia Zoological Garden. It will be used for the study and treatment of the diseases of animals and also for the study of comparative pathology. Dr. Charles B. Penrose is to be director of the laboratory and Dr. C. Y. White assistant director.

Mutter Lecture.—The Mutter lecture on Surgical Pathology was delivered at the College of Physicians, Friday, December 2, 1904, by Dr. G. H. Monks, Lecturer on Surgery in the Harvard Medical School. His subject was "Studies in the Surgical Anatomy of the Small Intestine and its Mesentery."

The Samuel D. Gross Prize.—This prize of $1,200 will be awarded on January 1, 1905. The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens." It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery, and that on the title page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery. The essays, which must be written by a single author in the English language, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 219 South Thirteenth Street, Philadelphia," on or before January 1, 1905. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The Committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The Committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

CHICAGO.

Resolution Placing Cook County Hospital Staff Under Civil Service Rescinded by County Board.—At a meeting of the Cook County Board, held November 25, the resolution offered at a previous meeting placing the medical staff of the County Hospital under the merit law was rescinded. The President of the Board, Mr. Foreman, promptly vetoed this resolution, and the Board decided to absolutely ignore him by ordering the disapproval placed on file. This confused state of affairs was the culmination of a meeting of the Public Service Committee, composed of all the members of the Board, which lasted all day, and at which physicians, both the opponents and the upholders of the civil service examination, were present and said what they had to say. It would seem from the remarks that were made that those opposing the application of the merit law to the County Hospital medical staff manifested jealousy of what they termed the domination of the medical branch of the University of Chicago (Rush Medical College) in the conduct of the hospital affairs. Dr. C. E. Humiston said "It is Standard Oil against Castor Oil." Dr. William E. Quine, Dean of the College of Physicians and Surgeons, the Medical Department of the University of Illinois, expressed his grievance against the way things were conducted at the hospital. In the last examination for internes, candidates from one institution triumphed when they appeared before examining boards from their own college, but showed only

ordinary ability when examined by members of other schools. He said, "The men who brought that condition to pass are now trying to pack an examining board in favor of one institution. I am opposed to that conception of reform." The President of the County Board was drawn into the discussion by Dr. Thomas A. Davis, who accused him of acting as dictator in the hospital affairs. He said there were at least six men in the room who heard the President of the Board insist on Dr. Billings' election to the position of President of the hospital staff. These adverse declarations were not allowed to pass without reply from the upholders of the merit law. Dr. Hugh T. Patrick defended the proposed examination, when a commissioner of the board interrupted him to ask his opinion about the opposition of so many physicians to the civil service examination. Dr. Patrick replied that "I cannot tell you all that I think about those doctors without being discourteous toward some of the estimable members of the profession."

Charge of Favoritism Answered.—The charge that favoritism would be shown toward men connected with Rush College by the examining board, as at present constituted, was answered by Dr. Frank Billings. Without descending to personalities, Dr. Billings made the following declaration: "In the constitution of the examining committees of the board on the main subjects, which are surgery, medicine, nervous diseases, children's diseases, and obstetrics, Rush College has a minority rather than a majority. In the committee on surgery there are five men, one from Rush, one from Northwestern, and one from the Physicians and Surgeons. The other two are outsiders, not connected with any college, but it so happens that all five are graduates of Rush. In the department of medicine the three examiners are Dr. Quine, Dr. Frank S. Johnson and Dr. Otto Schmidt. Rush has no representation on this committee. Northwestern and Physicians and Surgeons have one each, the other is unattached. Of the two men on the nervous disease committee, neither is a Rush college man, and the three obstetricians are divided between the three big colleges. The same is true of the committee on children's diseases and the committe on skin diseases. In pathology one is from Rush, one from Northwestern and one unattached. One man charged that out of forty-eight physicians and surgeons on the examining board thirty-eight were from Rush College. This statement was promptly corrected by Commissioner Walker. He declared that there were thirty men on the board, divided as follows: Seven Rush, seven Northwestern, five Physicians and Surgeons, two eclectics, two homeopaths, two dentists and five at large. The Public Service Committee, by a vote of 9 to 4, recommended that the county board rescind its action. This resolution was adopted despite the fact that the matter is before Judge Tuley on a petition for an injunction restraining the civil service commission from holding the examination. The board formally then accepted the recommendation.

Chicago Orthopedic Society.—At a meeting of the society, held November 22, the following officers were elected: President, Dr. John Ridlon; Vice-President, Dr. John Lincoln Porter; Secretary and Treasurer, Dr. Arthur B. Hosmer.

McCormick Memorial Institute for Infectious Diseases Receives a Donation of $100,000.—Mr. Otto Young has given this amount toward the endowment fund of this Institute. The philanthropic project is delayed pending proposed amendments to the hospital ordinance.

GENERAL.

Bubonic Plague Reported in Chile.—While the prevalence of bubonic plague has not been officially declared in Chile, it is stated that there are cases that the Chilean Government daily conceals in order that steamers may not omit touching at ports at which there are no sanitary regulations.

Existence of Yellow Fever Denied.—Dr. Carlos Finlay denies positively the existence of yellow fever in the island of Cuba. It was not within possibility, he said, that the half dozen Marine Hospital Inspectors stationed at Cuban ports should have discovered cases which the thoroughly organized Health Department of Cuba had failed to discover, and more than improbable that they should know of such cases and yet fail to call the attention of the Cuban department to them. Dr. Finlay said that the only yellow fever case originating in Cuba in more than three years was that of the American, Scott Fuller, at Punta de Sol, which was extremely light, and of questionable authenticity. Suspicion attached also to Fuller's attendant, but the disease had not developed. Health officers at all Cuban ports, Dr. Finlay said, treat all fever symptoms in arrivals from Caribbean and South American ports as suspicious, and also all others that are in the least questionable. Dr. Delgado, a Cuban, who is the United States Marine Hospital Inspector at Havana, disclaimed any knowledge of yellow fever cases this year, except in six persons, who arrived from Mexico, and who were immediately isolated. Of those two died and the others recovered.

Meeting of American Association for the Advancement of Science.—The University of Pennsylvania will be the scene of the greatest meeting of scientists in its history during the Christmas holidays. Arrangements have been made for forty different societies to convene here at that time, the university acting as the host to them all. The principal convention will be the fifty-fourth annual meeting of the American Association for the Advancement of Science, which will meet December 27 to 30. Ten of the forty societies mentioned above are sections of the American Association, while the other thirty are national societies, dealing with all aspects of science. The American Association will attract at least 1,500 delegates and educators. Carroll D. Wright, the Commissioner of Labor, has been selected to deliver the principal address, which will be made on December 28.

Massachusetts General Hospital.—The Zander Room at the Massachusetts General Hospital has now been open for patients since June 23, 1904, and its services are becoming more and more in demand for medical, surgical, orthopedic and nerve cases of all sorts. The old Bigelow amphitheater, left vacant by the completion of the new operating rooms two to three years ago, and since that time used only for clinics, has been entirely remodeled into a large, well-ventilated apartment, with a gallery and adjoining offices, and here are set up the 40 to 50 beautiful pieces of mechanism which go to make up the Zander apparatus. There are recording machines for lateral curvature and scoliosis of all kinds; machines for massage of every part of the body, from the little finger to the entire trunk; apparatus which can be operated by the patient—action move-

ments or by electricity—passive movements, for exercising every part, muscle or joint, of the human body, slowly or rapidly, with practically no force at all, or with a very powertul leverage. Patients come here to be treated from the hospital wards, the Out-Patient Department, and from outside physicians (in a few instances), the greater number of cases are naturally orthopedic, lateral curvature, scoliosis, weak backs, flatfoot, etc.; surgical cases, fractures, sprains in convalescent stage and arthritides of all kinds; new cases, anterior poliomyelitis and neuritis and medical cases; neurasthenics, neuroses and cardiacs recovering compensation. The entire department is under the direct supervision of Dr. Böhm, who came from Europe for this purpose. Every patient recommended for treatment is carefully examined and measured, recorded and then given a prescription, with the list of exercises or massage to be taken; the patient then, in charge of an assistant, goes through with his movements as ordered. Take a cardiac case for example: The heart, size, murmurs, etc.; lungs as to edema, and pulse as regards rapidity, volume and tension are looked over, and the patient given his list of exercises, which at first will consist of the lightest of passive movements. After the morning's work the heart, pulse, etc., are again examined, and in this way the progress of the case is gauged. Gradually the passive movements are increased and changed to active ones, more and more rigorous in character, until finally compensation completely restored, the patient is able to leave the hospital and take care of himself. The neuroses, myocarditis and fatty hearts seem to receive the most benefit from this treatment. For the most part the patients enjoy the work, and in almost every case derive great benefit from it, and their numbers are increasing daily.

Fourth Pan-American Medical Congress.—This congress will convene in Panama the first week in January next, and bids fair to be a most delightful midwinter trip. The delegates will leave this country by the Atlantic, Pacific and Gulf Coasts the last week in December. They will return by the same routes or will make round trips (see appended list of routes). The Public Health Association meeting will take place on the following week in Havana, and those desirous of attending both meetings, can arrange to do so. From Havana, the return trip can be made directly north to New York by water or via Miami or Tampa, Florida, or New Orleans. The connections and dates of sailing are now being arranged. The Panamanian Government has appropriated $25,000 for the scientific session and the entertainment. The congress will be held from the second to the sixth of January. The afternoons will be devoted to the scientific sessions and the mornings and evenings to trips and social functions. So far as can be learned, the program in Panama will be a reception on the first day, by President Amador of the Panama Republic, and the formal opening session of the congress the same evening. On the second day an excursion to the canal in the morning, meeting of the various sections in the afternoon, and a banquet in the evening; on the third day, an excursion down the bay to Taboga Island, where a Panama breakfast will be served, scientific sessions in the afternoon and a ball in the evening. On the fourth day, an excursion to the United States Army barracks in the morning, section meetings in the afternoon and the formal closing session in the evening. On the fifth day, in the afternoon, those of the congressists who intend going to Cuba to attend the meeting of the Public Health Association, will sail, while those who intend returning home by way of New Orleans or New York, will remain until the following Tuesday. The program of the Public Health Association will be an inviting one and of an important character. The Cuban Committees are making extensive preparations for the entertainment of the congressists. From the returns now coming in, it would seem that at least one-half of the members of the Public Health Association will make the round trip to both medical meetings. It is understood that the Pan-American congressists who do not belong to the Public Health Association will be invited by this Association to take part in their discussions as their guests, and that they will also be invited by the Cuban Entertainment Committee to participate in the festivities.

Dr. Rudolph Matas, of New Orleans, Secretary of Section of General Surgery for the United States, informs us that an arrangement with the United Fruit Company has been perfected by which a steamer of this line will leave New Orleans for Colon on Wednesday, December 28, 1904, at 10 A.M. (instead of Friday, December 30, at 11 A.M., as previously announced), which will reach Colon (Panama) on Monday, January 2, 1905, the opening day of the Congress. In view of the facilities offered to reach Panama via New Orleans it is expected that many will choose this route and those who intend to do so will please forward their names to Dr. R. Matas, Secretary of Section of General Surgery, No. 2255 St. Charles Avenue, New Orleans, La., not later than December 22, 1904.

Routes and Rates to the Fourth Pan-American Medical Congress in Panama, and the Public Health Association Meeting in Havana. (Combined Trip.)—The routes to the Fourth Pan-American Medical Congress are gradually narrowing down as more advantageous rates are being offered. Those who go only to the Pan-American Medical Congress will probably go and return by the way of New York or New Orleans. From the former starting point $100 will be charged for the round trip; from the latter point $50. By far the greater number, however, will make the round trip to both of these meetings, returning to Baltimore via Jamaica on the steamer which the commission is arranging to charter. The Di Giorgio steamship line of Baltimore, Md., offers special ship for exclusive use of party, including meals and berth, at sea and in ports, to Panama, Havana and return, attending both meetings and visiting Kingston and Port Antonio, Jamaica, for $130, providing fifty persons take passage. The Athos will leave Baltimore, December 27, 11 A.M., arriving in Panama January 2, P.M., or 3, A.M. Leave Panama January 7, A.M., arrive in Havana January 9, A.M. Leave Havana for Jamaica January 16, A.M., arriving at Baltimore January 18. The Athos is one of the staunchest of steel ships, with electric lights, running water, and all modern equipments in the way of toilet conveniences. She has a fine deck surface and a number of deck staterooms, and is guaranteed to be in first-class condition. The president of the Steamship Company will be one of the party on the trip. The members of the party can live on board when in ports if they desire, thus saving hotel expenses. Lunch and dinner will probably be served on deck when in smooth water.

Physicians can bring members of their families and friends at the same rates. All arrangements must be closed ten days before sailing date. Number of passengers limited to seventy. Application for reservation of staterooms, berths, etc., to be addressed to Ralph F. Nalley, 105 Park Avenue, Baltimore, Md.

Tuberculosis Investigation.—The imperial commission, appointed by the Government to investigate the relations between bovine and human tuberculosis, met November 26. According to the *Sun*, Dr. Weber reported that the investigations hitherto made showed that bovine and human bacilli were absolutely distinct biologically and one never develops or changes into the other. An examination of fifty-six bodies of persons who died of tuberculosis showed the presence of human bacilli only in fifty. There were bovine bacilli, however, in six, three of whom were young children. The surmise is permissible that the latter received the bacillus from the milk of a diseased cow. Two other cases, which Professor Weber regards as most important, were where corpses showed bovine bacilli in the glands and human bacilli also in other portions of the body. They were distinct cases of double infection. Another important case was that of lung tuberculosis where bovine and human bacilli were associated. The commission is reported to have reached the general conclusion that tuberculosis in human beings was caused by the human bacillus, but urges the careful use of all prescribed measures to prevent infection with the bovine bacillus.

The American Journal of Anatomy.—This journal was founded in 1901 for the purpose of collecting and publishing in a worthy manner contributions to the science of Anatomy emanating from American investigators. Since the inauguration of this journal, there have appeared two volumes containing about 500 pages each, with many text-figures and monochrome and colored plates. The titles of papers, including those in Volume III, are announced in this circular. The wealth of material at the disposal of the editorial board has insured prompt publication, and has made it possible to maintain a creditable standard. The presentation of the subject of anatomy has been representative of its various phases, including not only contributions on Human Anatomy, but also on Comparative Anatomy, Embryology, Histology, Neurology and Cytology, branches of the science of Anatomy which are so intimately bound up with the problems of Human Anatomy that they have been included within the scope of this journal. It was hoped by the founders of the journal that it would not only serve as a medium of publication for a worthy type of anatomical research, but would also tend to create a higher standard in anatomical work and attainment, and thus also advance the cause of modern scientific medicine. That his hope has already been realized in a measure seems reasonably assured. According to an arrangement made with the Association of American Anatomists, the *American Journal of Anatomy* has become the medium for the publication of the proceedings of this Association, together with abstracts of the communications presented at its annual meetings. The board of editors, realizing that the founding of a scientific journal could not be undertaken without some financial guarantee to defray the deficit which would, in all probability, be incurred for a number of years, have, in conjunction with a number of generous persons, subscribed to a reserve fund to insure a beginning. The regular annual subscriptions, together with this reserve fund, which is, however, available for only a limited period while the journal is becoming established, have enabled the board of editors to maintain the *American Journal of Anatomy* in its present form. It will be readily agreed, however, that the success of the journal can be permanently assured only by the continued support of its regular subscribers, and by further efforts of those who are interested in its welfare. The board of editors feel warranted, from the encouragement and support which they have thus far received, in expecting further additions to the subscription list from institutions and individuals who profit by the enterprise of the journal.

OBITUARY.

Dr. Henry M. Lyman, formerly connected with Rush Medical College, died in Chicago, November 21, after an invalidism of four years. The cause of death was angina pectoris. He was born in Hilo, Hawaiian Islands, November 26, 1835, and was graduated from Williams College, Massachusetts, in 1858, as valedictorian of his class. He began the study of medicine at Harvard Medical College, but graduated from the College of Physicians and Surgeons of the City of New York in 1861. After a short term as interne in a medical hospital, he entered the army and served as acting assistant surgeon from 1862 to 1863, being on duty in the military hospitals of Nashville, Tenn. In 1863 he established himself in practice in Chicago, paying special attention to diseases of the nervous system. From 1871 to 1876 he was professor of chemistry in Rush Medical College; from 1876 to 1877, professor of diseases of the nervous sytem; from 1877 to 1879, professor of physiology and of nervous diseases, and from 1889, professor and emeritus professor of the theory and practice of medicine in the same institution. He was also professor of medicine in the Northwestern University Woman's Medical School from 1880 to 1888. He was the author of a textbook on the "Theory and Practice of Medicine," which was published in 1892, and of numerous articles in the literature.

Dr. Nelson L. North, of Brooklyn, was stricken with a hemorrhage of the lungs at Gates Avenue and Broadway last week, and died shortly afterward. He was born at Elba, N. Y., in 1830, and studied medicine in the College of Physicians and Surgeons. He was the author of several medical works and belonged to the American Medical Association, the New York Academy of Medicine, and the Kings County Medical Society.

Dr. W. L. Coleman is dead at his residence in Austin, Texas, aged seventy-one years. He was an authority on yellow fever, having served through several epidemics and won a Howard medal, given in appreciation of his services in fighting this disease. During the Spanish-American war, Dr. Coleman was sent by the United States Government to make an examination of the yellow fever condition of Cuba. He was the author of a book on the disease.

Peculiar Electrical Accident.—According to the lay press a user of the telephone while talking pressed an electric button, and in some manner established a circuit and was rendered insensible from a resulting shock. The cause of the accident could not be ascertained.

CORRESPONDENCE.

THAT OPTOMETRY BILL AGAIN!

To the Medical Profession of the State of New York:

During the legislative session of 1904, a society of opticians known as The Optical Society of the State of New York, petitioned the legislature to enact a law creating a State board of examiners in optometry. Before this board would appear all persons who desired to practise optometry, which practice was defined in the act to be enacted as "the employment of any means other than the use of drugs for the measurement of the powers of vision and the adaptation of lenses for the aid thereof." The Medical Society of the State of New York opposed this bill, and with the aid of other organizations, especially the County Medical Societies and the Optical League (an organization of opticians doing a legitimate business), secured its defeat.

Since the last election, this optical society has been forwarding to physicians in all parts of the State, as well as to the members-elect of the next legislature, a document giving reasons why a law of this kind should be enacted and asking their endorsement.

At the time of the hearing on the Optometry Bill before the legislative committees of last year, the opticians presented a long list of names of physicians who had endorsed their efforts. The undersigned communicated with every name on that list, and learned that where reputable physicians had endorsed the measure it was through a misapprehension of the real purpose of the bill, and when its true character was pointed out to them, they not only withdrew their endorsements but in many cases wrote vigoroues letters in opposition to it. Many of the names were fictitious, the communications addressed to the addresses given being returned as not found. A large number were the names of irregular practitioners, as osteopaths, spiritualists and so on. There is no doubt that the object of the opticians in presenting the present arguments is to obtain the endorsement of physicians so that at the next legislative session these signatures can be used to offset the opposition which will be presented by the regularly organized medical bodies of the State. I therefore address the profession of the State, urging its members not only to refuse to endorse this and similar measures but to make an effort to present to their representatives, both in the Assembly and the Senate, the true merits of the case, and urge their opposition to it.

The arguments presented by the opticians are very misleading. Their claim, of course, is that they desire to protect the community from incompetent people, but the fact is (as every well-informed physician must know) that they are all incompetent. They seek to create a separate profession. This they deny, but in their remarks before the legislative committees they continually used the expression "our profession." They seek the legal right not only to apply lenses for the correction of defective vision which may or may not be due to errors of refraction, but they also seek to treat headaches, dizziness and the various reflex phenomena which may be due to affections of the eye itself or to affections of organs remote from the eye. They pose as being competent to make a differential diagnosis. To prepare physicians to do this work the law requires that a four-years' course in a medical college shall be taken, after which a medical examination conducted by the State must be passed. Physicians themselves find that after this preparation it is often difficult to be sure of one's ground; and, if this is so, there seems to be no good reason why opticians should be allowed to undertake the same work with any less preparation.

It seems unnecessary at this time to go into an extended argument in opposition to this bill. The effort to secure its enactment is not an honest one. Opticians know that they are violating the law in following the occupation which they are now engaged in, and they say that if their bill is enacted it will not give them any more powers than they now possess, while the fact is that the enactment of the bill will give them the legal right to do what they are now doing in violation of the law. They really desire to use the legislature as a tool to put them beyond the grasp of the law; and if this is once clearly brought to the attention of our senators and assemblymen, there is no doubt what the outcome will be. We have met this and similar efforts more than once in the past and there is no doubt that we shall meet many more in years to come; but from our experience we feel justified in making the assertion that if the medical profession will present a united opposition to measures of this kind, they will never be enacted into law in the State of New York.

Frank Van Fleet, M.D.,
Chairman of the Committee on Legislation of the Medical Society of the State of New York.

New York, November 23, 1904.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, held November 17, 1904.

The President, A. H. Smith, M.D., in the Chair.

The scientific business of the evening was under the auspices of the Section on Medicine and the first part of the program consisted of a demonstration of the Hoy Opaque Projector by Dr. H. Holbrook Curtis.

Stereoscopical Reflection.—The Hoy Opaque Projector enables the lecturer to demonstrate opaque objects on the screen, as does the stereoscope for transparent. The human hand, for instance, can be held at the focus of the lens and the representation of it made to appear on the screen. Any microscopical specimen may be demonstrated to a class in the same way. Pictures and illustrations of various kinds in books, even those that are delicately colored may be enlarged and reproduced exactly as they are.

Dr. Piffard, in discussing the Projector, said that some thirty years ago an instrument similar to this had been used by Professor Arnold. Owing to the fact, however, that a close examination always gave more information than such a demonstration, it proved not to be so useful as was anticipated.

Preservatives in Foods.—H. W. Wiley, Chief of the Bureau for Chemistry of the United States Department of Agriculture, then gave a preliminary report of the results of the investigation that has been made during the past year, with regard to the influence of preservatives and adulterants in food on the public health by the United States Department of Agriculture.

Dr. Wiley said (author's abstract):—"The point of view of the physician in respect of the use of preservatives in foods is somewhat different from that of the manufacturer or even of the general consumer. The term 'preservatives in foods' may justly include also coloring matters and certain edulcorants, such as saccharin and its compounds. The point of view of the manufacturer of food products relates to the preserving of the products in such a manner as to present them to the consumer in a practically fresh state. The view of the general consumer relates to the consumption of foods which are pre-

served in the manner indicated by the constituency which is in ordinary good health. The point of view of the physician includes also and particularly the effects of foods of this kind upon invalids and convalescents. It cannot be denied that good food is the principal weapon in the armament of the physician. As long as his patient can digest and assimilate a wholesome diet there is always hope of recovery. The very moment the digestive organs, however, cease to act, when the food which is given is no longer digested or assimilated, there is every reason to fear the gravest danger. Food, therefore, in this sense, is the most important element of the materia medica.

"In order that there may be no unnecessary discussion of certain points in connection with this investigation, I may state, without hesitation, that probably the great majority of healthy and vigorous people can consume a certain amount of food preservatives without any apparent ill effects. In the researches which we have conducted at Washington this has been illustrated time and time again. This, however, is not the important point of the investigation. It is not the purpose of an investigation of this kind to prove that every person who consumes preserved foods is subject to injury. The case is clearly made out, if those who are weakest and least able to withstand any unusual disturbance of the metabolic process suffer injury. Foods, in other words, are prepared for the whole people, the strong and the weak, and they should be so safeguarded that no added substance should be permitted which could work an injury on the least resistent.

"Nor do I think it is a sufficient answer to this statement to say that there are many conditions in which pure food itself, of an excellent quality, produces injurious effects. This, of course, can not be denied. Every physician meets in his daily practice many cases of this kind. The fact that foods of undoubted purity may themselves work injury is no argument in favor of admitting to these foods foreign and unnecessary substances which are in themselves injurious or become so when mixed with foods. For instance, we have shown in late researches in the Bureau of Chemistry, that cranberries contain large quantities of benzoic acid, in some cases amounting to the ordinary quantities of this substance used as a food preservative. The natural occurrence of benzoic acid in cranberries does not warrant its addition to those foods which do not contain it, nor does it warrant the addition of benzoic acid in cranberries themselves. Cassava, which is a common food product in the tropics and as far north as South Georgia, contains considerable quantities in its natural state of hydrocyanic acid. So great is the quantity of this poisonous substance in some of the varieties grown in the tropics that it is never eaten until it has been boiled for the purpose of drying off this poisonous substance. The occurrence of this poisonous matter in a natural food cannot be cited as a justification for adding hydrocyanic acid to foods in general. As is well known this same substance exists in peaches and apricots, especially in the pit, although in much smaller quantities than in the cassava. Nor can we admit, it seems to me, the arguments *de minimis*. The advocates of the use of antiseptics in foods, I believe, admit, without exception, that all of them in large quantities are injurious. They also cite what is perfectly true, that common salt in large quantities is injurious, and therefore they draw the conclusion that as common salt, which is an antiseptic, is not injurious in small quantities, and is injurious in large quantities; therefore, any other antiseptic, for instance, salicylic acid, may be judged of the same way. But this is not the case, as will be seen by a closer analysis of this argument. Common salt is a necessary constituent of human foods. It is acknowledged by physiological chemists to be the source of hydrochloric acid which is so necessary in stomach digestion. Hence, not only is it an antiseptic but it is much more a condiment and a necessary constituent of food. In fact, nearly all the condimental substances in common use, with the possible exception of the peppers and spices, are at the same time condimental and have, to a certain extent, a food value. This is especially true of salt and sugar. It probably is not true of vinegar, which is solely condimental and antiseptic, but is not of any appreciable value as a food. Alcohol is also condimental and preservative and has a distinct food value. The physician thus makes a broad distinction between antiseptics which are condimental and to a certain extent nutritive, and antiseptics which are non-condimental and non-nutritive. There can be no objection, therefore, to the proper use of common salt, of sugar, of vinegar, and of wood smoke in the preservation of foods. These bodies all reveal themselves by their taste or odor and thus a natural limit is set which prevents their excessive use. On the contrary, the other line of antiseptics and preservatives which are non-condimental, such as are represented by salicylic and benzoic acids and boric acid, practically have no taste or odor in the quantities in which they are employed, and hence the consumer is not notified by any natural property of these bodies of their presence. It appears, therefore, that here can be no justification from a dietary point of view in the addition of even small quantities of non-condimental antiseptics to foods. It might be granted, for the sake of argument, that if there were only one antiseptic known, its use in small quantities might be in certain cases allowed. For instance, in the case of salicylic acid, which many healthy persons can consume, even in considerable quantities, without any very great discomfort; if this were the only antiseptic used the *argumentum de minimis* might be allowed to stand. But when we consider that there are a half dozen, or perhaps more, non-condimental antiseptics in common use, all of which might be consumed in a single meal under certain circumstances, it is evident that the *argumentum de minimis* fails to apply, for if the consumer should eat six small quantities it would be equivalent to eating one large quantity.

"Again we find the argument used in favor of antiseptics of a mineral character, like boric acid and borax, sulphites, etc., to the effect that the presence of mineral salts is absolutely necessary to physiological processes. We all admit, I think, without doubt, that the metabolic functions depend entirely for their action on the laws of physical chemistry. Osmotic pressure, solution, translation through membranes, diffusion, etc., are the physical forces which develop the phenomena of living beings. But in this case it is not evident that any unusual and unknown substances are employed. We have, in common salt and the mineral salts which exist in ordinary foods, in the carbonates and the bi-carbonates which are probably formed during the metabolic processes, an entirely sufficient amount of mineral matter to secure the proper activity of all the organs. There seems to be, therefore, no justification for the

addition of other substances of a mineral nature to aid a process already sufficiently well secured.

"In the investigations which were made in the laboratory at Washington with boric acid and borax, distinct disturbances of the metabolic functions were disclosed. They were not of a great magnitude and might easily escape the ordinary observations. They were revealed, however, by the chemical balance in a most unmistakable manner. Even when a small quantity of boric acid was administered daily, not to exceed a half a gram over a period of fifty days, there was noticed a gradual loss of weight, a slight loss of appetite, occasionally a tendency to a feeling of fulness in the stomach and especially in the head, developing at times into a dull headache, a marked but not very distinct indisposition or inability to perform the ordinary mental exercise which the young men engaged in during their daily work, a disturbance in the phosphoric acid and nitrogen balances, an increase in traces of albumen which exists in certain cases in the urine, and other evidences of change which showed an effect which could not be regarded as otherwise than deleterious.

"On the other hand, when the preservative was given in rapidly increasing doses over periods of twenty days, beginning with half a gram and rising to as much as three or four grams a day, not only were the disturbances which relate to the changes in the balances, as indicated by the chemical analysis observed, but also marked symptoms of *malaise* and discomfort, loss of appetite, rapid loss of weight, occasional nausea, fullness in the head, bleary eyes, dull and persistent headache, inability to perform the ordinary mental duties, etc.

"Both of these sets of experiments lead to the same conclusion, namely, that while most healthy young men can take a considerable quantity of borax for a short period without any apparent discomfort, when continued for a long time or when rapidly increased in amount, distinct disturbances of metabolic activity take place. Marked symptoms of discomfort, though not amounting to real illness, are observed.

"Another point that must be considered is the fate of the added preservative in the organism. This we have studied very carefully both with borax and with boric acid, as well as with salicylic, benzoic and sulphurous acids. Only the data of the first two, however, are complete. The work shows that in round numbers 80 per cent. of the total quantity of boric acid and borax administered is excreted by the kidneys. Nearly all the rest of it is excreted through the skin. These data show very clearly where the burden of excretion lies. Furthermore, it was shown conclusively that neither boric acid nor borax undergoes any marked change in the body. Boric acid remains practically boric acid and the borax remains borax. It might be assumed with a good deal of probability that the boric acid would be neutralized to a certain extent by the alkaline bodies with which it comes in contact, especially in the small intestine and in the blood. On the other hand it might be reasonably inferred that borax would undergo more or less decomposition in the presence of the acids in the stomach. Doubtless both of these assumptions may be partly true, as it is rather difficult to affirm that there is no change at all in these bodies. It may be that a little of the boric acid is neutralized, forming a borate or bi-borate, and a little of the borax decomposes, forming free boric acid and a sodium salt, probably chloride or lactate. There is one point of judgment, however, which shows that little change takes place, namely, the effect of these reagents upon the acidity of the urine. During the administration of boric acid the acid in the urine was markedly increased while during the administration of the borax it was markedly diminished and in some instances an alkaline reaction set up.

"Aside from the points which are here presented, another phase of the subject must be considered, namely, the additional burden which is placed upon the kidneys. Of course, it may be said, as it doubtless will be, that the amount of this burden is very slight, but, as a rule, a great burden which produces a breaking strain is made up of increments of very small particles. I think it must be admitted without question that the kidney is a well worked organ ordinarily and has about all that it ought to be called upon to do. If you add to foods a half dozen different substances all of which are practically eliminated by the kidney you increase its burden to that amount. This increased burden does not seem to be justified by the good, if any, which is gained. It will not be denied by any one that practically every one of the substances used as antiseptics in foods may be, in itself, a very useful remedy in certain diseases. We know that borax and boric acid are largely used for remedial purposes and the same is true of salicylic acid, of benzoic acid and of formaldehyde. This, it does not seem to me, is a justification for the use of these bodies upon those who are perfectly healthy. In other words, drugs are not indicated except in cases of disease and where they are used for prophylaxis.

"Summing the matter up in the light of the experiments which we have conducted and of those which have been conducted by others, we admit first of all that there are many contradictory data which are difficult to reconcile. For this reason it seems rather precarious to base a definite conclusion upon experiments with one or two persons. The number in our experiments was twelve, and had there been facilities for caring for them it would have been better if the number could have been larger. It is only when we consider the data for all twelve as a whole that definite and reliable conclusions can be drawn. It must be admitted further that the mental state must be reckoned with in all experiments of this kind. But whatever particular mental irritation or excitement is produced, repetition and time will tend to diminish and even neutralize it. For a few days it is more than probable that the mental attitude will have a considerable effect, but when a young man sits down for an eight or nine months campaign of this kind he soon falls into a state where it is believed the mental attitude does not produce a very great effect. It might have been possible to control this to a certain extent by running a number of blanks, that is, having those upon the table who supposed they were getting preservatives and yet were really not. The limited number of subjects which we had at our disposal, however, seemed to indicate that this method of control would not be as valuable as to use them all for a direct experiment.

"Finally it may be said as a result of our experimental work, that there is every indication to lead us to believe that the use of boric acid and borax should not be forced upon any one. In those cases where it may be good it can be specially provided. They certainly should not be used with infants, invalids, convalescents, or those who suffer from any particular digestive idiosyncrasy. It should not, I believe, be put in foods of any kind except when they are plainly marked, and even not then except in special cases and for special purposes. What is true of boric acid and borax will probably be found

equally true though perhaps not to the same degree of all the other common antiseptics in use."

The discussion was opened by Dr. G. L. Peabody who said that in the section on legal medicine at Paris in 1900, Dr. Brouardel had declared that the amount of preservatives now being employed in food, was, to say the least, disquieting. Unfortunately the present methods of legal procedure are not such as to limit what evil there may be in the matter. The question usually put by the Court is, Would the amount of preservative known to be present in a given sample, prove fatal? Of course this question must be answered in the negative. In the same way, the administration of any poison might be proved harmless. If one one hundreth of a grain of morphine is recovered from the organs of a patient, this demonstrates the presence of the poison, but cannot be said to show that a sufficient amount was taken to produce death. In spite of all the symptoms of opium poisoning then, the legal decision may be in favor of a criminal. Dr. Peabody said that when a small amount of a substance was frequently repeated, it may have more injurious influence than if an equal amount were administered all at once. It was the teaching some years ago that a good sized dose of calomel, 10 to 20 grains, repeated once if necessary, given just after the initial chill of pneumonia and before the stage of consolidation could be demonstrated, might abort the pneumonia. In not a few instances, Dr. Peabody himself has given 20 grains and repeated the dose within twelve hours. All that resulted was a smart purgation without any serious poisoning affect. If, however, calomel were given in divided doses of say one-tenth or one-twentieth of a grain every hour until 20 grains were taken, salivation and other toxic symptoms would be so severe as probably to prove fatal. Dr. Peabody pointed out that the utility of foods depends mainly upon their instability, that is on their tendency to change easily and so be assimilated. Whatever hinders this tendency for food materials to change, impairs digestion. Hence the danger of food preservatives. This danger is all the greater because preservatives are more apt to be used in the food of the lower classes, who need all the nutrition they can obtain from their food and who are deprived of part of its beneficial influence by the slowness with which the gastric juice will act upon it. It is not as yet known how many anemias may be due to the fact that insufficient nutritive material is absorbed from the digestive tract to keep up blood equilibrium. In France there has been much discussion with regard to what is called plastered wine. A certain amount of sulphate of potash and plaster-of-Paris is added to wine in order to give it a dry flavor. Many good authorities consider that these materials are prone to produce a distinct tendency to cirrhosis of the liver. In at least one case, that has been under Dr. Peabody's observation, bottled beer, which had been prepared in some special way, proved a source of annoying digestive symptoms to a physician who had tried the experiment over and over again of using it after a quitting of it for a time and had always had a return of his symptoms.

Old Persons.—The danger of substances accumulating in the system is especially great in old persons. Brouardel showed by experimentation that at the age of twenty-five years, if a gram of salicylic acid were taken, its elimination began one hour after ingestion and was practically complete after twenty-four hours. At the age of forty-four years, however, it was several hours before elimination began, and it was at least two days before the last of the acid had disappeared. At the age of sixty-five years, elimination did not begin until the second day and took many days to complete. Therefore it is dangerous to have any substance frequently given to old persons if there is any tendency for it to accumulate. Certainly boric acid and borax cannot be considered entirely harmless. A five per cent. solution in the pleura and in the case of a lumbar abscess has been known to prove fatal. Even less than this has given rise to very serious symptoms in cases of dilated stomach when boric acid solution was used for washing out the stomach once or oftener each day for a prolonged period.

Boric Acid in Therapeutics.—Some years ago boric acid obtained a reputation as a remedial agent in epilepsy. As a consequence, it was used, either in combination with the bromides or by itself, in considerable daily doses for long periods. It was then proved to be a distinctly dangerous drug. It seemed to be especially irritant to the kidneys, and patients suffering from any kidney disturbances at the beginning of the treatment soon proved intolerant to its prolonged employment. Even in patients, however, and except for their epilepsy, who seemed to be perfectly healthy at the beginning of the boric acid treatment, symptoms of uremia sometimes developed. The mere stoppage of the administration of the drug did not always prove sufficient to put an end to these unpleasant complications. Fatal uremia, even was not unknown. It is very evident that the experience of physicians all over the world is entirely opposed to the thought that boric acid, even in doses usually not considered large, can be considered harmless, if it is taken for a long time. This of itself would seem to be enough as regards the use of the substance as a preservative for food materials.

Difficulties of Investigation.—Dr. Darlington, Commissioner of Health of New York City, said that many complaints are received with regard to supposed adulterated food, but that it is extremely difficult to secure evidence of the presence of enough poisonous material for purposes of prosecution. Besides, the department is not ready for extensive investigation in this line. Often it is found that in cases of supposed poisoning of food, patients have really died from some disease. This is not infrequently the case with regard to terminal kidney disease or with regard to such affections as cerebrospinal meningitis. Of course, under conditions, such as have recently been exploited, in which wood alcohol is added to whiskey, serious results lead to the detection of the poison. It seems clear, however, that wherever any chemical preservative is added to food, this fact should be stated plainly on the label. With regard to milk, however, it seems utterly inadvisable that any preservative should be allowed. No antiseptic can make up for proper cleanliness of milk. New York draws her milk supply from a distance of four hundred miles in some cases, but the only preservative needed is ice. The local government board in London allows the addition of borax to cream and butter, but this seems only to leave a path open for the use of preservatives and other material.

Milk Preservation.—Dr. Rowland Freeman said that for a time it was thought that preservatives might be permitted in milk. Whenever this substance is properly handled, however, that is put on ice, shortly after it is obtained, there is no need of any chemical preservative. As a matter of fact, permission to use it will surely result in serious inconvenience to the children of large cities.

Increase of Gastric Disorders.—Dr. E. E. Smith said that it seems not unlikely that the increase of gastric disorders, which has been noted in recent years, may be due to the fact that preservatives have been

used more than was suspected. This is especially true for the increase of acidity which has become so common a complaint, especially in the case of neurotic individuals. It seems not unlikely that the effort of the stomach to overcome the alkaline food preservatives leads by reaction to an increase of the gastric acidity beyond what is necessary. In experiments with borax upon animals, Dr. Smith found that a special tendency to the production of irregular tufty patches of hair was produced, so much so that the borax animals could be picked out at once. As the borax is excreted through the skin, it seems not unlikely that it is the irritation of its presence near the hair follicles that causes this result.

Experts Differ.—Dr. Piffard said that in a case in which he was asked to give expert testimony before a legislative committee, he found that a distinguished professor of physiology told the senatorial committee that borax was absolutely harmless in food. Notwithstanding this, the law was passed forbidding its use. Since then judges have thrown cases of conviction out of court because they insist that there is no evidence of the poisonous effect of such substances. It seems clear that there is much more danger in whiskies than has been thought. Wood alcohol is present much oftener than might be imagined. The especial flavor of Scotcy whisky, which is now so popular, is said to owe its flavor to amyl alcohol. The German spirits, made so extensively from potatoes, differ entirely from grain spirits and are likely to prove more harmful.

Formalin in Milk.—Dr. Jacobi said that Von Behring now announces that all tuberculosis in children is due to the use of milk containing infectious material. He proposes to treat all milk with formalin, which will kill these germs and eradicate tuberculosis. He seems to consider formalin harmless. Another German observer, however, has shown that the lab ferment, that is the active agent in the digestion of milk, becomes absolutely useless in the presence of eevn a small amount of formalin. Hence, if formalin is to be employed very generally, children may be protected from tuberculosis, but they will develop nutritional affections likely to prove much more serious. The use of formalin as a food preservative is now known to have produced an epidemic of dermatitis, two cases of which proved fatal in the English army. Its origin was unknown at first, but on its recurrence, it was traced to the milk supply, one part of which contained formalin and the consumers of which suffered while those fed from the other milk did not suffer. Prof. Gerhardt used to advise small doses of boric acid several times a day as a remedy for adiposity. He was an excellent observer and a conservative physician and it was on the strength of the results obtained, that he continued to use it for many years. Dr. Jacobi himself has employed it for this same purpose with excellent results. It seems to prevent an accumulation of fats and to cause fatty material to be eliminated that would otherwise be stored up in the system. He has never found it advisable to give more than two grams a day and usually one gram has sufficed. It is evident that the constant use of this material by persons who, instead of wanting to lose, wish to gain weight, would be eminently inadvisable. With regard to bottled beer, Dr. Jacobi has known one case in which some fluorine was present. It did not occur in draft beer of the same kind. This brand of beer is still manufactured and does not seem to have been improved any in this respect.

What Preservatives?—Dr. Andrew H. Smith said that it is very hard to draw the line as to what is and what is not a proper preservative. Salt has been used so long that there is now no objection to its employment. Saltpeter is mixed with all brines and yet though we know it to be a virulent poison, no serious objection to its use has ever been known. Instead of having vaguely poisonous affects, this depresses the heart and irritates the kidneys very definitely. Nearly the same thing may be said of the preservative element in wood smoke, that is creosote. As a matter of fact few people use enough of such preserved food to notice any serious affects. Elimination prevents accumulation and so saves the individual. Silver salts may produce argyria, yet the occasional use of half a grain of nitrate of silver is an excellent therapeutic measure in certain cases of indigestion. It would be necessary therefore to be sure of definite knowledge with regard to harmfulness before suggesting legal regulations in the matter.

Dangers of Preserved Food.—Dr. Smith said that it must not be forgotten that for certain varieties of preserved food there is constantly some danger of ptomain poison. In such cases the use of a mild antiseptic may prove of great service without doing any harm. After a recent gastronomical experience, in which he indulged in some *pâté de foies gras*, he experienced all the bother that might result from ptomain poison. No amount of persuation could convince him that it would not have been better for him to have had a few grains of borax or boric acid with the preserved meat, even though it might involve some little delay of digestion or some slight irritation of the kidney, provided it would ward off the serious and painful symptoms. Therefore, it seems better that the chances of possible injury should be weighed against present customs in the manner of eating and a truly conservative course followed. With regard to cold as a preservative, Dr. Smith acknowledged that ice was indeed a very valuable preservative, but that it must not be forgotten that ice cream, as a source of poisoning, had in recent years become very familiar. It is possible for frozen material not to be aseptic and where toxins have already formed in such material, the freezing does not destroy them.

Premium on Filth.—Dr. Wiley, in closing the discussion, said that to permit preservatives to be used in milk is almost sure to put a premium on filth. The main element for the preservation of milk must be thorough cleanliness and then a degree of cold that keeps whatever bacteria that may be present from growing rapidly. In this matter it must not be forgotten that while the presence of such preservatives prevent the growth of bacteria, they do not neutralize the ptomains already present and that therefore much of the danger of the infected material in them as well as those from the presence of the preservative itself. With regard to *pâté de foies gras*, Dr. Wiley begged to say that the specimens so far examined in recent years by the government laboratories failed to disclose liver as a constituent of this material, which is so much in favor with the gourmet, but always showed veal present in large abundance. It is to veal in poor condition and not to any supposed tendency of the liver to disintegration that the President of the Academy may attribute his symptoms. With regard to wines, Dr. Wiley said that in order to secure a dry flavor, so much sulphate of potash and other material was employed that sometimes the wine smelt more strongly of the sulphurous fumes of the lower regions than of the bouquet from the vineyards of the hillsides of Provence or Burgundy, which it was supposed to bring with it. Notwithstanding this fact, French authorities are prone to insist on American acceptance of French wines and resented any criticism of the so-called preservatives employed for giving them a flavor which was supposed to add to their value.

THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, held October 6, 1904.

The President, R. C. Norris, M.D., in the Chair.

The Immediate Repair of the Cervix.—Paper by Dr. Barton Cooke Hirst. He states that the above title is a misnomer, as experience has demonstrated that the intermediate repair of the cervix after the fifth day gives the best result. This fact dictates the time for the repair of all the pelvic injuries, if the cervix must also be repaired. Trachelorrhaphy can be performed with perfect success and without morbidity or mortality during the puerperium. The specialist who criticizes the operation as to safety or success, either is prejudiced or incompetent. He performed the operation in more than 150 cases at the University Hospital, and practises the procedure in his private and consulting work. The question arises, how can the community at large be offered the advantages of specialistic attention for lacerations incident to childbearing. The writer's solution is for the poorer classes to be confirned in well-appointed and intelligently-managed hospitals, and for the wealthier classes to be attended by their family physicians under the supervision of a specialist, who could deal with complications in labor, examine the patient during the puerperium, repairing whatever damage has been done, and make the final examination at the end of the puerperium. He considers that the plan is one that appeals to the general physician as practicable and desirable.

Dr. E. E. Montgomery, in the discussion, said he had listened with much interest and pleasure to the two papers upon the immediate closure of lacerations of the cervix and perineum. It certainly must be apparent to every one that the ideal method of procedure is the one which would restore the organs of the parturient woman to a condition similar to what they were prior to the occurrence of her labor. When one realizes the various sequelæ that are likely to result from failure to unite lacerations of the cervix or perineum this is still more evident. Subinvolution of the uterus, the increased size of the organ which must result where a prolonged convalescence takes place following a delivery, the increased danger of infection that is present, the long train of symptoms that arise as secondary results of such conditions make it extremely desirable that the part should be repaired at as early a date as possible. He can understand that the cicatricial changes that follow in these structures will be of such a character as to render it difficult at a later date to overcome the alterations which have occurred and to restore the parts to a normal condition. In operating he agrees with the readers of the papers as to the great importance of thorough asepsis in every step of the procedure, making sure that there is no opportunity for introduction of infection. One can understand that the possibility of infection must influence our procedure as to whether it shall be immediate, intermediate or, at a later date. If he were engaged in the practice of obstetrics he should endeavor to so practise that he would be able to repair at once injuries that have taken place. As a gynecologist, who is likely to see these cases sometime after the delivery of the patient, he should be anxious to know something of the methods of procedure of the obstetrician in attendance, prior to restoring to immediate repair of cervix, vagina, or perineum. If he knew nothing of his methods, he should hesitate about the immediate repair of such lacerations. He said he had knowledge of a number of cases of lacerations of the pelvic floor where the immediate repair was made, in which aseptic precautions had not been employed by the attendant upon the case, and in which sepsis developed, and in which it was necessary to remove sutures to give the patient a chance for recovery. He recalled seeing a case some years ago in consultation with some three physicians, and he was to decide as to the advisability of removing the uterus. On examination he found that there had been a bilateral laceration of the cervix into the lateral fornix to the peritoneum. There was laceration of the perineum to the sphincter. The perineum had been repaired with the result that the tissues were bathed with a lot of decomposing material and the woman had a high fever. Instead of doing hysterectomy he advised that the perineal sutures be removed, and the entire cavity irrigated and packed with gauze. He was called a few hours later to find the patient with a temperature of 106° F. She, however, subsequently recovered. He had seen other cases in which the immediate repair of the perineum has been followed by a large amount of necrotic tissue between the sutures, no union taking place and the necrotic tissue giving rise to danger from the absorption of the putrescent material rendering the condition perilous. Objection is sometimes made to immediate repair of the cervix from the fact that the parts are so relaxed that the sutures have to be tied firmly, and owing to the rapid involution, the parts become loosened and union does not result. The classical case spoken of by Montrose A. Pallen is well known, in which he immediately repaired a laceration of the cervix and had good union. The immediate repair of the cervix would lead in some cases—but he does not know that this is an objection—to the performance of an operation which would, with ordinary aseptic precautions, prove unnecessary. The profession knows that, in the great majority of primagravidæ, laceration of the cervix to a greater or less degree occurs. At one time, at the Philadelphia Hospital, the doctor examined every patient delivered and found laceration had occurred in every one; and, in the great majority of the cases the laceration healed spontaneously. He fully agrees with what the last speaker has said regarding caution in making proper apposition of the muscles. Such care will add very greatly to the comfort of the patient. He is fond of catgut in all plastic operations on the vagina. The acid secretion of the vagina, however, will give rise to more rapid disappearance of the catgut than is evident in other parts of the body, so that the ten-day catgut will not last that long in the vagina. He prefers the chromicized gut prepared to last twenty days. In some cases he had found that catgut prepared for a short time has been absorbed too soon and there is stretching of the parts and formation of cicatricial tissue. If the vagina and perineum are to be operated upon he would feel it absolutely necessary that the operation should include every laceration in the genital canal, that he cervix and the vaginal walls should receive prompt attention as well as the laceration of the perineum; otherwise, there would be danger to the patient from the accumulation of material in the vagina giving rise to septic processes.

Dr. John G. Clark said he had been much interested in the two papers presented this evening, for they bear upon practical subjects which have recently been discussed before the meeting of the

American Gynecological Society in Boston. If one were to designate the various times at which a lacerated cervix may be repaired he should speak of them as: first, the immediate, within a few hours after the delivery; second, the intermediate, five to ten days after confinement; and, third, the more remote, at any time after the completion of the puerperal period.

Fifth Day Repair of the Cervix.—Dr. Dickinson, to whom Dr. Hirst has referred, read a paper on his experience relative to the fifth day repair of the cervix. In general he advocated waiting five days for the repair of all lacerations of the cervix, except in the three following classes of cases: (1) Those in which there is a profuse hemorrhage from the laceration; (2) those in which there had been bilateral incisions, such as in the Dührssen operation; (3) those in which the cervix is low in the vagina and may easily be reached at the time of the perinorrhaphy. In the discussion of the immediate and more remote repair of the cervix, one must first take into account the time when injuries to the perineum are sutured. Dr. Davis, in his paper, advocates the immediate repair of the perineum under careful operative technic and Dr. Clark believes he has struck the keynote when he insists upon the latter point, for the same care should be observed in these cases as in any other surgical procedure. First, as to the wisdom of an immediate repair of the perineum. For several years the consensus of opinion has been entirely in favor of prompt attention to vaginal lacerations at the completion of parturition. When the bad surroundings are taken into consideration, under which these operations are necessarily performed and the uniformly good results following these repairs, he does not believe a general departure from this custom is justified. If under unfavorable conditions these results follow, one may expect even more perfect healing of these sounds when treated as Dr. Davis described. If it is admitted that the perineum should be at once repaired, then he can see but one conclusion, and that is that the cervix should be either immediately repaired in meeting Dickinson's primary indications, or if deferred, at a more remote day after the puerperium is completed. Certainly the primary conditions noted by Dickinson, indicating the immediate repair, are well grounded and he should unquestionably adhere to them. Concerning the five-day intermediate repair he is, however, skeptical as to its ultimate value. One sees so many cases in which healing occurs most satisfactorily when left alone that he can see no reason for reversing this almost universal observation and the teaching upon this point. If primary healing is not satisfactory the more remote trachelorrhaphy is so good, that to break into a woman's early convalescence and throw her house into turmoil six days after her labor by giving her ether and subjecting her to an operation in these early days at a time when the milk secretion is fairly established and the baby is nursing well, is not justified by the surgical exigencies of the case. It is preferable, therefore, that either an immediate repair or, in the event of delay, a trachelorrhaphy be performed at some more convenient period after the completion of the puerperium.

In the discussion of the immediate repair, before the American Gynecological Society, Clifton Edgar, and Cragin, of New York, Williams, of Baltimore, Craig, of Boston, and Wakefield, of San Francisco, all expressed opinions opposed to the immediate repair of a lacerated cervix. Cragin admitted that it might be done by skilled hands successfully, but that he could not sanction this teaching to students.

While he has no doubt that these injuries, if repaired in a well-equipped maternity hospital, will do well, yet the vast number of labors in this and all countries occur in private houses, in the majority of which there are no facilities for the more careful work required for repairing a lacerated cervix. While it would be ideal to have all women confined in maternity hospitals, or if in private houses to have an expert in consultation, the domestic environments of the parturient woman are usually such that this will never be the case, consequently one must consider these operations from the standpoint of the conditions under which they will usually be performed. Therefore, he believes that if the immediate or five-day repair were generally to be adopted, not only could the morbidity but also the mortality of puerperal cases overbalance the good which this procedure might do, if solely confined to the hands of the specialist. He considers, however, that Dr. Hirst is quite justified in carrying out this procedure in a maternity hospital, but agrees with Cragin and others that the teaching of this doctrine is hazardous. If it is the right course to pursue it should be quite fully sustained by not only the immediate but the more remote operative results, which will subsequently be reported from obstetrical clinics. Until that time this procedure will be open to discussion.

Dr. Stricker Coles said, in taking up this discussion, he wished first to speak of his own results. He has, for the last ten years, closed all lacerations of anterior and posterior vaginal walls and in the cervix, if the tear was large, immediately after labor; had not had to delay the closure in a single case for twenty-four hours, for he prepares for it before each delivery. His results in closure of the cervix have not always been good. They are better now than when he began, for then he did not appreciate fully the elongated condition of the cervix and its rapid involution. The stitches should be placed at the uppermost part of the tear, but should not be placed too far down, as the lumen of the cervix will be narrowed, and the flow of lochia will be retarded. So far he has not had any cases of infection of subinvolution, and may class the result fair with no inconvenience to the patient. His results with immediate closure of the perineum, pelvic floor and anterior vaginal wall have been most satisfactory, even when the tear was complete. The cases operated on in very poor surroundings and with very little care have done well. Dr. Davis has gone very carefully over lacerations of the vaginal wall and he can add nothing, but wishes to emphasize the importance of bringing muscle to muscle, and to do this the buried suture is often necessary to bring the retracted ends into direct apposition. The great objection to immediate closure is the swollen and edematous condition of the parts. This he tries to obviate as far as possible by watching his cases and not allowing the tissue to become devitalized by prolonged pressure. He considers the healthy epithelial cell the best barrier against sepsis and always tries to protect and to keep its continuity. He has had no experience with the intermediate closure of lacerations and will await the results of others to see whether sepsis will not be more frequent when raw surfaces are left exposed for five or ten days, also what will be the effects of an operation at this time on the mother's milk. This method

does not seem applicable to the greatest number of cases as they cannot afford to pay for this extra operation, for obstetrical cases now pay very poorly if they are properly attended. If the method is taught to students, many cases will not be closed at all, for deferring the operation for five or ten days, it will be neglected or rejected. When done immediately the operation takes a very few minutes, causes the patient no inconvenience and slight pain, and gives almost as good a result with the cervix and equally as good with the perineum, pelvic floor and anterior vaginal wall, and can be applied at home or in the hospital to the rich or poor.

Dr. E. P. Bernardy said, in regard to the immediate operation, the query has been in his mind, Why should not lacerations of the uterus be sewed up as well as lacerations of the perineum. It can be done readily. He has done it and the results have been very good, without elevation of temperature and the patients recovered with good results. In the treatment of these cases there must be created a thoroughly good field of asepsis. Needle, catgut and everything should be properly prepared, even at the bedside of the patient before being used. Under those circumstances the results will be good. He has never operated at the intermediate or five or ten-day period, but since hearing Dr. Hirst's paper he would not hesitate to do it. He thinks the patient would get along better than to run the chance of healing. Some lacerations of the cervix, as is well known, do heal, but only about twenty-five per cent.; the other seventy-five per cent. either are operated on or the patients live with lacerated cervices. Lacerations of the perineum he stitches immediately after the birth of the child. He recollects one case in which he was called in consultation in which twenty-two stitches were used in the vagina and perineum, and in which on the ninth day the patient left her bed entirely well, and without a sign in the perineum and vagina that there had been in laceration. Therefore, he thinks one ought to stitch at once. In very bad cases where the parts are mutilated and blue and black, always try to bring the tissues back to their normal condition by douching with warm saline solutions before stitching and the results will be invariably good.

Dr. George M. Boyd said that this subject is of great interest to everyone practising obstetrics. If he understands Dr. Hirst's paper, he does not believe in the immediate repair of the cervix. That is the consensus of opinion. Dr. Hirst repairs the cervix after the fifth day. Every obstetrician repairs the cervix. If it bleeds a stitch or two are put in it. It seemed to him that it would be bad teaching to tell the average family doctor, who must be an obstetrician, to sew up every cervix. As Dr. Montgomery has stated, upon examination one finds that nearly every case has laceration. The debatable point is the intermediate operation, and Dr. Boyd has not had experience with that kind of operation. The satisfactory results of Dr. Hirst, however, would tempt one to try it. He feels that it is the duty of the obstetrician to get the patient in the best possible condition before she leaves the maternities. He agrees with the doctor in that he does not believe the average maternity has been sufficiently careful in the past to bring about the proper repair of injuries after labor.

Dr. O. Hopkinson, Jr., said he thought it would be extremely unfortunate if the young graduates were instructed to repair the cervix immediately after labor. The tears, in his experience, have been bilateral and the anterior lip is much larger, edematous and more easily reached than the posterior. In one case a man without much experience in repair of the cervix after labor tried to pull the posterior down even with the anterior, and of course, tension was so great that he tissues gave way. Therefore, he thinks, that the repair of the cervix immediately after delivery is one which ought to be done by some one with experience. He thinks it safer, unless a hemorrhage confronts one, to leave it alone for five days (with which operation he has had no experience yet), or, until later on.

Dr. Theodore A. Erck said that the point in the question of the immediate or intermediate repair of the cervix is, how much is the woman going to be benefited. If every young man is taught that he should repair every laceration of the cervix immediately or intermediately, Dr. Erck believes many cervices will be repaired unnecessarily. Two of the gentlemen have spoken of the difficulty of making a good immediate repair of the cervix. The young graduate has not usually at first all the advantages of practising where the necessary aseptic detail can be carried out. Many of these men will become expert in a year or two, but how much will womankind have to suffer as a result of that operation? This should be considered. Dr. Erck places stitches for laceration of the perineum at the termination of labor. The obstetrician has seen and operated on cases in which the result of the primary repair was a failure and Dr. Erck would like to suggest the substitution of silkworm-gut for catgut in these operations so that the operator will see the result of his operation during removal of the stitches.

Dr. Richard C. Norris apologized for leaving the Chair to take part in the discussion. He said, in the first place, he thought one must consider the intermediate operation from two viewpoints: (1) Its practicability; and (2) its results. Here one must view the practice of obstetrics from its highest plane and study the question especially from the standpoint of results. Whether the operation is practicable in private practice, in the hands of the average doctor, is an open question. It has been the experience of most men in the past, that the immediate operation for laceration of the cervix, unless done for the special indication of hemorrhage, is not a justifiable one. When the intermediate repair is chosen patients examined on the sixth,seventh or eighth day of the puerperium, the cases of spontaneous healing of the cervix will be found to be pretty well advanced, and the experienced surgeon would not operate on such a case. If spontaneous healing has not occurred, he operates at this time, and those who have done this work know that it can be done successfully. Operation on the cervix after the sixth or seventh day, in Dr. Norris's own experience has been quite as successful as occurs in the later operations to which Dr. Clark referred. This question is discussed from the standpoint of what capable surgeons can do. If equally satisfactory union follows an intermediate operation, and it certainly does, what advantages can accrue to the patient by delay? Dr. Clark speaks of getting excellent union at the remote operation, but in many of the cases, while the wound in the cervix united, the uterus has undergone chronic interstitial changes, and there has been evolved a train of symptoms which often persist and would not exist, if the cervix had been repaired at an early date.

Viewed from the standpoint of results, the intermediate operation upon the cervix can be depended upon to give as good union as the remote and by the early operation one spares the patient a train of ills. That the immediate repair of the cervix is not satisfactory, is the opinion of the men who have had the widest experience; the intermediate operation can be and is a successful operation, as shown by those who have had experience with it. When one approaches the study of the best time for the repair of the perineum and pelvic floor one again has to view it from the standpoint of results. If it can be demonstrated that better results will follow an immediate operation than can be obtained by the intermediate operation, then Dr. Norris thinks it must be taken for granted that the immediate operation should be done, and the advantage of the intermediate cervix repair must be abandoned. Viewed from past experience the immediate operation has been a success. If it can be demonstrated that the operation on the perineum has no disadvantages by being delayed and that equally good results can be obtained then the combined intermediate repair of both cervix and perineum will be the ideal treatment from the surgical standpoint. This question narrows itself down to a matter of personal experience. Only those men who have done the operation are in a position to criticize it. Dr. Norris propounds these questions: Is it justifiable to allow the patient to wait? Is there added danger of infection? If the obstetrician is not surgically clean, if he has carried dirty fingers into the vagina, if he has not conducted the labor with the highest grade of asepsis and antisepsis, he had better not operate either immediately or after a few days. If he has carried infection into the woman's vagina, sewing up the perineum at once is not going to protect her. It should be determined by actual experiment whether there is any detriment to the patient to allow her perineum and pelvic floor to remain unrepaired for six or eight days. Those men who have tried it, say there is no disadvantage to the woman. There would not be so many secondary operations, if the average doctor did not neglect to at once repair these cases, and yet their patients so neglected seldom have serious infection. The severest cases of infection, as a rule, are not the ones of lacerated perineum that have been neglected. The infection is in the uterus, not the vagina. Dr. Norris is convinced that the intermediate operation has no serious disadvantage, and from his experimental knowledge, acquired with the desire to test this question, he believes there is no disadvantage in a clean case in allowing the perineum to go unrepaired for the length of time necessary to obtain good results for the repair of the cervix. As to results, he has been wonderfully surprised. One would expect that there would be failure of union, but in the cases in which he has operated, that has not been the case. A man must put his theoretical objections to the practical test before his opinion has real value. If this question is studied from the standpoints of instruction of students and what the average practitioner will do, its practical value to them is questionable, because the average practitioner and the recent graduate are not skilled operators. If he gets bad results in the primary operation he will get bad results in the intermediate. He had better do the best he can with immediate repair of the perineum and when the patient is convalescent, send her to a gynecologist for reasonably early repair of the cervix. Dr. Norris believes as time goes on the new generation of doctors will be well prepared for clean surgical and obstetrical work, and that intermediate operation on both the cervix and pelvic floor will gain in popularity with the profession. Among the more intelligent class of private patients, appreciation of the ultimate gain to the patient will offset the natural objections on the part of the patient and her family of an anesthetic and a formal operation following so closely the anxiety of the confinement.

Dr. B. C. Hirst remarked that this question cannot be decided by theorists, but only by men with large practical experience. His own experience with reference to the cervix and perineum coincides with Dr. Norris's. Until three and a half years ago Dr. Hirst believed it a bad plan to attempt too much in the way of repair, but he happened to run across Lusk's statement regarding repair of the cervix and he saw one or two articles scattered through medical literature advocating primary repair, so he determined to try it. As a result of that trial, for three and a half years, in an experience comprising more than 150 cervical operations alone in the University Maternity, besides a number in other hospitals and private practice, he is in a position to recommend the procedure. As far as the instruction of students is concerned, it seemed to him to be the duty to teach students to do the best. Fifty or sixty years ago the average practitioner was not able to use the forceps. One old graduate told Dr. Hirst that when he left the University some fifty years ago to settle in the country, he took an obstetric forceps with him, and that an old practitioner having a case of adherent placenta sent for him to bring those new-fangled instruments and see what he could do with them. He thinks that in the near future the majority of physicians in general practice will do this work well, or they will not do it at all. In the University Maternity more than 50 cervical operations are demonstrated every season, done usually at the end of the week, to a class of about ten men each, so that each man acts as assistant in about five cervical operations. It seemed to Dr. Hirst that these students ought to be prepared to do this work as it should be done. There seems to be some confusion as to why the intermediate operation should be preferred. He first thought the immediate operation was the better one and he tried it in 40 or 50 cases, but found that there was too large a percentage of fever after the repair of the cervix immediately. While it was fortunate that there were no serious or fatal cases of sepsis, there was a higher proportion of morbidity than should prevail in a well-managed maternity. After the intermediate operation this tendency is not observable.

Dr. Clark referred to the discussion before the American Gynecological Association. The mere statement of the views of the men who took part without any explanation might lead one astray. Those gentlemen who criticized the procedure adversely have never tried it. Taking this fact into consideration, one can better judge of the value of some of the remarks that were made. Dr. Dickinson is right in many particulars, but wrong in one, when he says that if the perineum must be repaired then the cervix also should be immediately repaired. There is no harm whatever in letting the perineum go to the end of a week. The man who says that, because the perineum ought to be repaired early, the cervix ought to be also, is wrong. Such an opinion is not

based on correct observation, and perhaps, not on sufficient clinical material.

Dr. E. P. Davis said he had not oberved the absorption of No. 10 catgut alluded to by Dr. Montgomery in puerperal cases. It seemed to Dr. Davis the reaction of the lochial discharge is not the same as that in the vagina of a woman not parturient. Regarding the repair of the cervix, he had had some experience and much interest in one aspect of the question, that is, in the immediate repair of the cervix; and, by "immediate" I mean within an hour after the expulsion of the child; not immediate in the sense of twelve or twenty-four hours. In a certain class of cases, the results have been satisfactory. The cases are watched through the entire labor and the tissues are not allowed to become nodular, edematous or bruised. When delivery occurred, frequently under forceps, the entire genital tract up to the internal os was inspected for lacerations. If lacerations of the cervix were found more than one-quarter of an inch, they were closed; so were lacerations of the pelvic floor and perineum. Dr. Davis has seen no fever following this style of procedure. He has seen a considerable number of very satisfactory union in the cervix, and, of course, a very high percentage of union in the pelvic floor and perineum. Those cases were in good hands and the operation was practically immediate. The so-called, intermediate, or five or seven day operations, is on trial. When that is proven to be a successful procedure he shall be glad to follow it. He sees no reason why it should not be successful in many cases, but the matter comes down, especially to his own mind, to this: Is obstetrics to be done as a makeshift, a disagreeable necessity by the practitioner, to eke out his living; or, is it to be a surgical specialty? A large number will fall into all sorts of unskilful hands, and in such hands, the least interference, the better; but, if obstetrics is to take the place of a surgical specialty, then the students will develop an individual aptitude for practice, and some will take up medical work; others will do surgical work, and those students will be competent to perform operations on the genital tract, whether it be done within an hour, in ten or twelve days or in two or three weeks, and the work will go to those men. It ought to go to them, and the sooner the better.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

Stated Meeting, held October 21, 1904.

The President, Homer Gibney, M.D., in the Chair.

Congenital Scoliosis.—Dr. Reginald Sayre presented this case. He said that the baby came to the Clinic when it was three days old, and a short time after that a photograph and also an X-ray picture had been taken of the spine, which has congenital lateral curvature. These are not seen frequently, and Dr. Sayre thought the case sufficiently interesting to present. The picture was not very good, he said, on account of the difficulty in keeping the child still. The only possible way to do this was to hold the child by the arms, and in the efforts to keep it still the lateral curvature was straightened out. The skiagraph shows very sudden angling laterally, at about the eleventh and twelfth ribs, where there is coalescence of the ribs on one side, and rather marked gaping on the other side. Dr. Sayre said he remembered showing a patient a number of years ago, before this Society, that had lateral curvature, which, according to the mother's statement, was traumatic, this baby having been a transverse presentation and apparently having suffered separation of the ribs from the costal cartilages. On the right side the lower ribs almost touched the pelvis, and the upper ribs were up under the axilla. The mother said the condition was present from the time of birth—that a great deal of force had been used at the time of delivery. In this case there is no history of similar conditions, as far as can be ascertained. This baby has a large left inguinal hernia. The baby has stretched out a good deal on its contracted side since it was first seen. Dr. Sayre had instructed the mother to manipulate the baby, stretching it out, and it had been kept in a sort of cradle on its contracted side, stretching it out. An apparatus had since been used somewhat like that employed in the after-treatment of toricollis, pressing against the head, and making pressure against the chest walls on this bulging side. (Indicating). The child's right thumb has been almost amputated by intra-uterine bands. The baby is now nine weeks old.

Dr. Homer Gibney said, the interesting feature to him had been the angular deformity with the marked lateral curvature. He had seen a number of them, but he did not remember having seen one with such marked angular deformity.

Dr. Sayre showed another case, a boy, asking for diagnosis. He came to see Dr. Sayre a couple of weeks ago, the mother stating that he had limped for a few weeks previously, and complained of some stiffness in his hip. There was pain in the left shin, apparently no atrophy, possibly slight shortening of left lower extremity; not positive about this. Symptoms more marked at present than when boy was first seen. Nothing had as yet been done in the way of treatment, as it was desired to have the boy first seen by the members of the Section. The mother said nothing wrong had been noticed about him until a couple of weeks ago, when he started to walk lame. Dr. Sayre said he made a diagnosis of something the matter with his left hip, but he thought probably he had had a fall and chipped his acetabulum, or injured it in some way which showed very little on the outside, but caused him to have a slight limp. He was very much surprised on taking an X-ray to see that the head of the femur presented a honeycomb appearance, the upper half being almost destroyed. It was astonishing to see such a slight limp, and pain for only a few weeks, and such slight restriction of motion, and yet have such an extensive destruction of the femoral head—a process which had evidently lasted many months, judging from the condition of the bone as shown by skiagraph. Dr. Sayre said he recollected a similar X-ray shown by Dr. Frauenthal years ago, of a boy who had had a tuberculous hip with an enormous abscess, and who had recovered with a certain amount of shortening, but a large range of motion, the boy running around at the time, with a very useful leg. On looking at the picture, one would have imagined the only thing to do would be to scoop out the entire joint. It looked like a large sponge in the X-ray picture. The boy had more than two-thirds of the proper motion in his joint, and with the exception of the shortening, had a very useful leg. He proposed in the present case to apply a long traction hip-splint to free the diseased femur from weight bearing.

Dr. Homer Gibney said that it seemed extraordinary to find a boy with flexion, ad- and abduction, none of the motions interfered with except slightly, but to find an X-ray showing destruction of the head of the bone—the appearance of a coxa vara.

Dr. Myers said, in regard to the case of congenital scoliosis that he had never seen such a marked case. These cases were rare and the few he had seen had proved very difficult to correct. It had taken a good many years. In this case the lateral deviation was very marked, but the rotation very little in comparison. He asked Dr. Sayre his opinion as to the possibilities of the curvature of the spine having been produced by injuries.

Dr. Sayre said he would suppose it was quite possible there may have been some intra-uterine disturbances, the right thumb was amputated by an intra-uterine band, in all probability, and there may have been some other bands which caused the marked deformity of ribs and vertebræ. It is not at all the ordinary type of lateral curvature one sees in later years, but a wedge-shaped condition of two vertebræ, causing an abrupt twist in the spine with little rotation, leaving the child partly broken in two. The mother says it was a more or less difficult birth, but no instruments were used.

Dr. Myers said, in regard to the second case, boy with injured hip, that he thought there was some limitation of every motion except flexion. It certainly was most remarkable to find such good motion and function with such extensive destruction of the upper half of the head. This erosion, together with the lessened inclination of the neck, must represent a shortening of three-quarters of an inch, which has been entirely compensated for elsewhere, as there is no shortening by measurement from anterior superior spine to interior malleolus.

Hallux Valgus.—Dr. Sinclair Tousey presented this case, with X-ray pictures of that and other cases, and read a paper describing this operation.

Dr. Sayre, in the discussion, said he had been very much interested in the case of hallux valgus, and congratulated Dr. Tousey on the very good result. In looking at the pictures, it seemed to him it is generally seen in these cases that it is not really a hypertrophy of the head of the first metatarsal bone so much as a subluxation of the phalanx on the metatarsal bone, and theoretically he imagined that a division of the ligaments and replacing of dislocated bone would be the better operation. So far as he knew, no one had done this, although for the past six or seven years it had been suggested at various meetings. Before the days of X-ray photography the projecting subluxation of the head of the metatarsal bone was supposed to be an exostosis. Until it is looked at in the X-ray picture, one would imagine there was simply an abnormal distance between the first and second metatarsal bones, and subluxation oft he first phalanx on the first metatarsal bone. The practical results of the bone operation leave nothing to be desired. He had done operations on cases somewhat after the manner described by Dr. Tousey, and the results had been so good that he had not tried replacement of the subluxation after division of ligaments, although theoretically it would seem to him to be required in these cases. It has been found more sensible to utilize the abnormal articulation by cutting the bone behind the articulative surface, as Dr. Tousey has done.

Dr. Myers said that Dr. Keller, in the *New York Medical Journal*, of October 15, spoke of the dangers of destroying the tripod of the foot; the resulting deformity, weakness and painful callosities were as bad as the original condition. Excision of the head of the metartasal bone would cause the loss of the inner support, so he recommended the excision of the base of the first phalanx instead. In the case presented by Dr. Tousey, there was very good support on the inside, there was no pain and no fatigue in walking, so the objection mentioned did not apply to the operation he described. Dr. Myers had operated by this method, and the results had been satisfactory. Valpius (*New York Medical Journal*, October 8, 1904) said Weid had, in a number of such cases successfully transposed the extensor tendon to the inside of the great toe.

Case of Multiple Exostoses.—Dr. Myers presented this case, with skiagraph. R. F., twelve years old. His mother and her sister have exostoses on their tibiæ. Patient has two healthy brothers. There is no history of injury or muscular strain. There are large exostoses upon or near the epiphyseal lines at the lower ends of both femora, tibiæ, fibulæ and radii, at the upper extremities of both humeri, tibiæ and fibulæ, also at the junction of rib with cartilage anteriorly of the second rib left, and seventh, eighth and ninth on right. The tumors are multiform, nodular, like ridges or spiculæ. They have only been noticed for two or three years, and while growing have not as yet interfered with function. They are painless.

Dr. Sayre said, in the discussion on Dr. Tousey's cases, that cases of congenital injury were to him very interesting. They have been described as congenital dislocations a number of times, but all those that had come under his personal observation had apparently had fractures associated with the dislocation. Those cases do not seem like congenital dislocation of the hip in that respect, and the results of treatment that he had had or seen in the hands of others, have not been remarkably favorable. Several cases he had seen reported at the societies did not seem to him to be very much improved as to range of motion after operation compared with range of motion that he had seen in them prior to the operation. He had recently endeavored to reduce one by manipulation, and thought he had improved the child very materially at that time, but since removing the dressing, he thought he had not noticed a great gain; although the position of the head in relation to its glenoid cavity was improved, he did not think the range of motion materially increased over what the child had when the head of its humerus was articulated in the new glenoid it was excavating for itself behind the original one.

Dr. Tousey said that in radiographing the spine the light was above the abdomen, the patient lying on the back, the X-ray tube being directly over the median line of the body and over the center of the plate. He thought one reason for his success in getting the detail of the spine was that he had the patient in a position similar to the lithotomy position, which obliterated the hollow of the back and brought the lumbar vertebræ in contact with the photographic plate as well as the dorsal and sacral portions of the spine. In addition he made use of a "board compressor" of his own device, thin enough to be perfectly transparent to the X-ray, placed flat across the abdomen and strapped down so as to

press upon the abdomen and make the thickness of tissue three inches less than that which the X-ray would have to penetrate without this appliance.

In reply to a question by Dr. Sayre, Dr. Tousey said that the plate was exposed exactly two minutes.

Dr. Twinch said that Dr. Osgood, of Boston, in endeavoring to get a good picture of the spine, hit upon the plan of pressing a tomato can very heavily into the abdomen, in that way getting a very good detail of the spine.

Dr. Homer Gibney said, the Chair would like to compliment Dr. Tousey and say as to operations on hallux valgus that he had the pleasure of meeting Dr. Tousey this summer, and asked him to read a paper and show cases before our Section, and then narrated a case on whom the same operation had been done, except that the speaker usually used the lateral incision, and found a lot of hypertrophied tissue—bunion—he excised that, then closed the wound, using a pad between the first and second toes. A number of these cases had been done with most gratifying results. The shoulder case was interesting. One is at a loss to know just exactly what to do with these shoulders injured at birth or during labor; they are numerous at Clinic or Dispensary, and, as Dr. Sayre truthfully says, great trouble is experienced in their management and the results are not brilliant. Dr. Tousey said, in closing the discussion, that Dr. Jäger was right about the result immediately after operation being a better looking foot than it is some months later. This patient's last foot was operated on five months ago, so the present result is probably a permanent one. Dr. Tousey said that he could, however, see, on recalling the looks of the two feet immediately after the operation, that they have decidedly deviated from the straight line. At the time of the operations, he had those two toes in an absolutely straight line with the metatarsal bones. In regard to the possibility of straightening such feet without a bone operation, he had experimented some little time on the feet by traction, measurements, and so on, to see if any division of the soft parts would promise a better result, but he found that the ligaments, etc., were so short that he had to divide some of them even to accomplish the rectification which he had accomplished. Combined with osteotomy, he had to make a slight incision in the fibrous tissue. The man stands on his feet eighteen hours a day, handling baggage. He is one of the fellows that break our trunks, etc., at the Grand Central Station, so that the functional result for the present is certainly very good and according to the outlook bids fair to be permanent

Dr. Homer Gibney exhibited an apparatus devised at he Forty-second Street Hospital by one of the staff, for the application of spicas, single and double. We all know how difficult it is to get the shoulders and hips on the same plane, and this is a little scheme of his, to overcome the difficulty. It can be altered according to the size of the child, and length of limb. The apparatus is used at the Dispensary every afternoon, and it is used in private practice. It is giving general satisfaction. Dr. Eickenburg, the designer of the apparatus, is at present in Chicago, assisting Dr. Ridlon. It is a very simple device—a modification of the Lorenz hip rest. It is made in the shop at the hospital. It has been in ure for some time now and promises to give excellent results.

BOOK REVIEWS.

The Principles and Practice of Gynecology. By E. C. Dudley, A.M., M.D., President of the American Gynecological Society; Professor of Gynecology, Northwestern University Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago, etc. Fourth Edition. Lea Brothers & Company, Philadelphia and New York.

So much has been said in praise of the previous editions of this excellent gynecological treatise that the last edition might well be accepted on trust. The grouping of the subjects has almost without exception met with the unqualified approval of teachers and students. The usual manner of grouping all the diseases of some special organ in one part has not been followed, but the author has treated the various subjects from the standpoint of pathological and etiological sequence. The main subjects are grouped under four heads: (1) Infections and Inflammations, (2) Tumors, (3) Traumatisms, (4) Displacements. In this classification the author has well emphasized the functional unity of all the reproductive organs, and allowed a study of pelvic diseases in the combined forms they ordinarily assume. The first section of the book is devoted to general surgical and gynecological principles set forth in careful detail, an essential to the student, a valuable reminder to the surgeon. A special chapter is devoted to the disorders of menstruation and sterility. The entire volume is abundantly illustrated, and is to be commended in that the surgical instrument catalogue element has been eliminated. It has evidently been the author's aim to show the instruments as they appear in actual work. All important manipulations and operations have been illustrated to show the steps of the various procedures. The work is thoroughly practical, based largely on clinical experience and in the main conservative. The volume in general supports the author's claim that it is suitable both for students and practitioners, although it is perhaps unwise to make a universal statement to the inexperienced that the occasional use of the intrauterine sound or dilator may stimulate the menstrual flow without a word of warning, as has been done in the chapter on amenorrhea. The wisdom of the author may also be questioned in that he states that adhesions and contractions of a retroverted uterus may be stretched or broken by manipulations without mentioning the dangers of breaking up adhesions out of view or the possibility such a procedure might have of injuring diseased adnexa. The small number of personal cases cited is a pleasing feature of the book.

Physician versus Bacteriologist. By Prof. Dr. O. Rosenbach, of Berlin. Authorized translation by Dr. Achilles Rose. Funk & Wagnalls Company, New York and London.

In this somewhat controversial discussion we find an excellent summary of the pros and cons of the bacteriological doctrines.

The author's chief theme seems to be that an undue proportion of attention is given to bacteriological methods and not enough to ordinary clinical methods. We cannot see that the points brought out are of much real value at the present time—but they place the readers *en rapport* with the attitude of the skeptic of ten to fifteen years ago.

The work will repay reading by the overenthusiastic laboratory worker who would neglect the patients for the microscope and test tube, and there are many excellent features of the book apart from its argumentative and disputatious undertone.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 85. NEW YORK, SATURDAY, DECEMBER 10, 1904. NO. 24.

ORIGINAL ARTICLES.

THE IMMEDIATE REPAIR OF THE PELVIC FLOOR AND PERINEUM.[1]

BY EDWARD P. DAVIS, A.M., M.D.,
OF PHILADELPHIA.

WE may for clinical purposes accept the division of the pelvic floor into the anterior and posterior segments. Lacerations of the anterior segment are not infrequent in proportion to those of the posterior segment, occurring in about the ratio of one to three.

The attention of the obstetrician is usually drawn to this accident by the occurrence of hemorrhage. When the uterus is well contracted, when inspection of the cervix reveals no laceration with bleeding, and when torn vessels in the posterior segment of the pelvic floor are not bleeding, persistent hemorrhage is caused by a laceration of the vulva or anterior segment of the pelvic floor. Upon inspection, a positive diagnosis is readily made, when such lacerations are detected extending into one or both sulci, externally near the urethra or internally behind the symphysis pubis. The detection of these injuries high up upon the anterior vaginal wall behind the symphysis may be difficult. Following the bleeding which accompanies such tears, the operator will come upon the source of the loss of blood. In extreme cases these lacerations may threaten the urethra, and may be complicated by tears in the veins in the vulva from which severe hemorrhages may occur.

The treatment of this condition may be expectant or by serre-fines or by suture. Where infection is absent, small lacerations in the anterior segment will heal without apparent injury. If such lacerations are of considerable extent, the important fascia of the pelvis will be torn and prolapse and dislocation of the urethra and vaginal wall will result. The treatment by serre-fines is unsatisfactory and has been employed chiefly in foreign hospitals. The primary closure of such injuries by fine or medium-sized chromicized catgut under antiseptic precautions gives satisfactory results. With the patient in proper position and with good light, there is rarely difficulty in closing these tears. We must be careful, if the tear extends near the urethra, to avoid injury by suture. Where extensive lacerations high up occur, it is often impossible completely and accurately to close the entire laceration. One or two sutures of medium-sized catgut buried deeply enough to include the fascia will be of great service in preventing prolapse. While applying sutures, if the operator is annoyed by oozing from the cervix, uterus or pelvic floor, the vagina may be temporarily tamponed with gauze. Where the laceration extends near the urethra, a sound or catheter may be placed with advantage as a guide to the passage of sutures.

Lacerations of the posterior segment of the pelvic floor naturally divide themselves into tears of the pelvic floor and those of the perineum. The diagnosis of perineal tears is readily made by inspection, but the recognition of injuries to the pelvic floor requires especial care in exposing the deeper tissues. Where injuries are severe, blood may clot in deep tears of the pelvic floor, giving to the examining finger the sensation that the vaginal wall is intact. To make a thorough examination and diagnosis, the patient must be placed upon the back or side at the edge of a bed or table, the labia separated and the pelvic floor raised for inspection. This may be accomplished by the use of tenacula, or, more conveniently, by placing the longest finger of one hand covered by a rubber glove in the rectum and raising the pelvic floor by this finger. The other hand may use sponges and antiseptic solution, removing accumulated blood and exposing the full extent of the tear. Such injuries are rarely accompanied by considerable bleeding, as the vessels, if torn, retract readily. The extent and importance of lacerations of the pelvic floor must be estimated by the presence or absence of injuries to the deep fascia and the sphincter of the bowel. By thoroughly exploring the parts, the operator will be able to detect the extent of these lacerations.

Lacerations of the posterior segment may be closed immediately or after some delay. If the tear be considerable and the condition of the patient bad, the operator may wisely delay such repair for twenty-four to thirty-six hours. It must be remembered that we cannot accurately foretell the length of time required to repair lacerations. If the patient is greatly exhausted and the conditions are unfavorable for rapid work, it will be much wiser to delay until the patient has obtained rest and the conditions are favorable.

No considerable tear of the pelvic floor can be satisfactorily repaired with the patient upon a low bed and in a poor light. The patient should be placed upon a table or high bed in a good light, and sufficient assistance obtained to give the patient the care necessary for an important surgical operation. Partial or complete anesthesia is often necessary, and even if such be not employed in the beginning, it may be required before the end of the operation.

[1] Read before the Obstetrical Society of Philadelphia, October 6, 1904.

Sterile instruments, sterile gauze and suture material, antiseptic solutions, stimulants for hypodermic use, sterile appliances for the operator and at least one thoroughly competent and experienced nurse are required. The patient's limbs may be supported by assistants, or more conveniently by a sheet or sling passed beneath the neck, over the shoulders and tied about each leg on the outer side above the knee. If this be properly applied, the limbs are well retracted, the knees and thighs rotated outward and the patient placed in the most convenient posture for operation.

The most important stitches in closing lacerations of the pelvic floor are those placed at the highest points in the tears in the sulci. Considerable difficulty may be experienced in placing these stitches, and a fully curved needle is usually required to pass them. They may be placed one-eighth of an inch from the upper end of the tear, and should extend sufficiently deeply to pass through the connective tissue and fascia lying beneath the mucous membrane of the vaginal wall. After the first, stitches may be placed one quarter of an inch apart until the pelvic floor has been brought together and evidently raised toward its original position. At this point, the operator may with advantage turn his attention to the tissues near the sphincter of the bowel. If the muscle has been torn, it should be brought together by one or two fine catgut buried stitches. Where the muscular tear is extensive, fine catgut may be used for the muscle only. In all cases, muscle and connective tissue should be brought together by a firm and carefully applied stitch. There is no objection to using several stitches, provided the catgut be not too large and the stitches be properly placed.

Next comes the repair of the perineum, beginning nearest the anus and bringing together the skin edges and underlying fascia with silkworm-gut stitches, taking a considerable portion of tissue but without tension. The perineum should be closed up to the point where the posterior vaginal wall begins. No effort should be made to repair the fourchette, as bringing together the tissues in this region too closely will produce a pocket favoring the retention of lochia. When the perineum has been closed, a few stitches may be required in the lower portion of the pelvic floor. These should be of catgut and complete the repair. In this operation a perfect result may not be obtained from one of several errors in its performance. If the pelvic floor sutures are continued upon the perineum, the posterior wall of the vagina will be brought downward and a prolapse of the vaginal mucous membrane will result. If stitches are drawn tightly, especially those in the perineum, they will cut. If sufficient tissue be not taken in stitches, a superficial union only may occur.

In complete tears, the rectum may first be closed by continuous suture of No. 1 chromicized catgut prepared to last ten days, the stitches passed into the connective tissue, turning the mucous membrane into the bowel. A careful approximation will turn but little mucous membrane into the intestine and secure a good application for the stitches. The fascia and sphincter muscle of the bowel may then be accurately closed and then the pelvic floor and perineum as in an incomplete tear.

Several sorts of suture material are in use for this operation. Chromicized catgut prepared to last ten days, No. 2, has given good results in the sulci of the pelvic floor and where but one stitch was required in the fascia and muscle of the sphincter of the bowel. For closing the anterior segment of the pelvic floor and the rectum, No. 1 catgut of the same sort has been useful. In the skin perineum, silkworm gut has given satisfaction; occasionally two weeks catgut chromicized has given good results with great comfort to the patient. Sutures may be tied or shotted, silkworm-gut sutures having the ends left long and tied together to prevent irritation. From its ready adaptation to the tissue, silk would be an ideal suture for the skin perineum were it not for its unfortunate tendency to further the burrowing of bacteria in producing stitch abscess.

Complications may follow the performance of this operation. Hemorrhage usually ceases when stitches are tied. Should it persist, pressure may be applied upon the perineum by a firm pad of gauze, and a gauze tampon may be used in the vagina. Very rarely the operator may be obliged to take out stitches or to twist or ligate bleeding vessels. Hemorrhage after this operation is fortunately of rare occurrence. Infection is not of great rarity and may occur independently of infection in the uterus or a general septic infection. Thorough asepsis prevents this complication in most cases and the avoidance of strong bichloride solutions is a matter of some importance. The mucous membrane of the vagina should be injured as little as possible by antiseptic applications. Bichloride solutions need not be stronger than 1/4,000 or 1/6,000, and lysol one per cent. or normal salt solution are efficient upon mucous membrane. If the operator brings the tissue in good apposition without empty spaces, he does much to prevent the development of infection. The posterior vaginal wall should not be brought together through the fourchette as lochia may be retained and decompose in the pocket so formed. Just before stitches are tied, the parts may be flushed freely with antiseptic solution. In complete tears, the free use of salt solution on the mucous membrane of the bowel, tends greatly to prevent infection. Sterile and bichloride external dressings, prompt and thorough irrigation of the stitches in complete lacerations when the bowels move or the bladder is emptied are all essential. Tearing out of the stitches is a complication sometimes seen where the patients suffer con-

siderable pain after the operation or where the stitches have been brought together too tightly. For pain the use of opium will usually prevent the tearing out of stitches. If stitches have been brought together too tightly, a wound may sometimes seen where patients suffer considerable pain after the operation or where the stitches. Where there is great edema, the application of hot sterile compresses or irrigation with hot sterile salt solution may be useful. A wound is sometimes imperiled by the stitches catching in the dressings. If silkworm-gut stitches be brought upward to one or other side when dressings are applied, this accident is usually prevented.

In the presence of infection, the stitch at the site of infection must be removed as soon as possible and the parts thoroughly irrigated with an antiseptic solution. Vaginal douches should be avoided in these cases because of the danger that the douche may carry infective material from the perineum upward to the cervix. It is an interesting obeservation repeatedly made that puerperal septic infection by uterine or constitutional infection may develop while wounds in the perineum and pelvic floor heal by primary union.

The after-treatment of these cases consists of surgical cleanliness so applied as least to disturb the tissues and parts which are healing. We prefer the use of antiseptic solutions by pouring rather than by spraying or sponging. Small metal pitchers of convenient size are readily obtained which can easily be boiled and from which the antiseptic solution desired may be poured over the parts. They may then be dried by cotton or frequently require no drying, as the vulvar dressing soon removes the excess of fluid. The use of the catheter after this operation should be as brief as possible, and after two to three days in the most extensive cases its employment should cease. If the tissues be thoroughly irrigated with normal salt solution or any dilute antiseptic after the bladder is emptied, no harm will follow spontaneous micturition. The old custom of locking up the bowels after these operations has largely passed away. After complete tears, the rectum may be kept quiet to advantage for forty-eight hours and after that daily movements of softened fecal matter should occur. By thorough saline irrigation of the stitches and rectum such movements will not cause complications. Very rarely do the patient's limbs require restraint and only in extensive lacerations where the patient is restless when she wakes from ether. The removal of silkworm-gut stitches may take place from the seventh to the fourteenth day, while catgut requires no removal. Very rarely the knots of catgut stitches remain indefinitely to the patient's annoyance, but such are easily removed by irrigation or by a pair of dissecting forceps.

After the operation for complete tear, fistulæ may remain between the vagina and rectum for some time. Fluid may pass between these cavities and the operator may be disappointed in the failure to obtain complete union. If care be exercised in aseptic precautions and saline flushing, these fistulæ will close spontaneously and their presence will delay but slightly the patient's convalescence. After the stitches have been removed, and before the patient is allowed to take active exercise, she may assume the knee-chest posture twice daily to advantage in cases where the uterus is larger than normal and where a tendency to prolapse of the vaginal walls is present. The average patient after such an operation, where union occurs without infection, is convalescent in from three to six weeks. In cases where but partial union occurs, so soon as the first stitches have been removed a good result can often be obtained by curetting thoroughly the unhealed parts of the laceration and by inserting stitches a second time.

In estimating the success of an immediate operation the vaginal walls must be completely or nearly in apposition and without prolapse. There must be good control of the sphincter of the bowel and the patient must be free from pain, especially when using a closet or commode or when moving about. There must be no considerable vaginal discharge coming from the sutured tissues. Observation has shown that complete union of the perineum is much less important than that of the pelvic floor. If the pelvic organs are in good position without prolapse, the vaginal walls in apposition without prolapse and the patient has good control of the bowels without pain, a practical cure has resulted, although union in the perineum may not have been complete.

RECENT ADVANCES IN SURGERY.[1]

BY CARL BECK, M.D.,

OF NEW YORK;

PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING SURGEON, ST. MARK'S HOSPITAL AND THE GERMAN POLIKLINIK.

While surgery has to report no epoch-making discovery of recent date, many improvements have been made on some of our older methods.

For treating *congenital fistula* of the *neck* König advised first mobilizing the fistula by dissection to a point above the digastric. It should then be liberated by the finger to a point close to the mucous membrane of the mouth by dissecting bluntly, the oral cavity being kept wide open by a Whitehead speculum. A curved probe is now introduced into it through the wound to a point very close to the tonsil. Then the mucous membrane of the oral cavity is incised and a silk thread fastened to the external end of the fistula. Now the mobilized fistula-tract can be pulled into the oral cavity, where it is fastened to the wound margins of its mucous membrane. The projecting part of the fistula is then removed.

The connection between the integument and

[1] Read at the Annual Meeting of the American Therapeutic Society, June 3, 1904.

the fistula is thus cut off, and the remainder of the latter simply represents a harmless opening in front of the tonsil. The same method can be utilized in blind internal fistula.

The use of the *bronchoscope* for extracting foreign bodies has proved to be extremely valuable. Garel, of Paris, reports the case of a young woman who, three months previously, had aspirated a steel pin with a glass head. Kilian's bronchoscope was introduced through a tracheotomy opening, and by its aid the pin was seen, point upward, in a bronchial tube of the third order. It was extracted by a forceps. (The bronchoscope is much more useful after several skiagraphic exposures have been made. Ref.)

One of the most remarkable advances of recent date is represented by *Sauerbruch's air-*

Fig. 1.

Recurrent sarcoma of leg four months after operation. (See nodule in right gluteal region.)

chamber, which eliminates pneumothorax in intrathoracic operations. This is done by excluding the atmospheric pressure during the operative procedure, thus preventing collapsing of the lungs after being opened to the air. In a lower animal Sauerbruch opened the thorax on both sides, and removed sternum and ribs without seeing the respiration interfered with in the slightest degree. The Sauerbruch chamber is air-tight. Its size permits of the presence of surgeon, assistant, patient, and operating table. The head of the animal may project outside, while a rubber-cuff is tightened around his neck. Regulation of the air pressure is done by an air pump, a valve in its wall permitting the entrance of a sufficient amount of air to keep up continuous negative pressure inside the chamber. Professor von Mikulicz and his assistant, who did some work inside of the air-chamber for an hour, did not suffer any discomfort. The chamber is composed of boards, which are lined with tin, soldered at the corners. The roof is made of glass.

ABDOMINAL SURGERY.

In the surgery of the *biliary passages* many valuable contributions were received. The admirable work of Kehr and Mayo deserve special attention. One of the remarkable events was the successful removal of the aneurism of the hepatic artery by Kehr.

Interest in the various types of appendicitis and the technical steps of appendectomy is still undiminished, and it is interesting to note that American doctrines are more and more adopted in Europe as far as the pathology of the vermiform process is concerned.

Many of these European surgeons who used to ridicule the "American hyperactivity" are now enthusiastic advocates of early interference in appendicitis, and this number is growing larger from day to day.

In order to facilitate operative procedures in the *hypochondriac* and *epigastric* regions, Marwedel tried to turn up the rib-arch, considering that the rigidity of the thoracic margin interferes with the access to the superior hepatic surface. The same applies to the lower portion of the esophagus and to the dome of the diaphragm. The *modus operandi* is as follows: By a curved incision, running parallel with the costal margin, and extending from the xiphoid process to the tenth rib, the abdominal wall is divided. The rectus muscle as well as the external oblique are separated from the internal oblique and the transversalis. The cartilage of the seventh rib now comes in view, and is divided at its sternal junction. In the same manner the junctions between cartilages and bone of the eighth and ninth rib are exposed, and divided by blunt dissection. By retracting the loosened portions of the ribs and the soft tissues over them over the chest, access is now gained to the hypochondrium.

The same principle of procedure can be utilized on the left side for approaching the cardia and the upper part of the stomach.

The disturbance caused by *adhesions* and *peritoneal bands* have recently received more thorough attention. Lejars, the excellent French surgeon, has made a special study of these important conditions, which frequently show their clinical manifestations by vague functional disorders, only so that they may not be recognized. The patients are often regarded to be neurasthenics. Later pain may be a predominating symptom, and finally, even strangulation may be produced. Sometimes after an apparently slight abdominal injury vomiting, pain, colicky attacks and symptoms of obstruction may turn up. Exploratory laparotomy will clear the situation, and

detaching or excising the constricting bands will promptly remedy the disorders. Lauenstein and Gersuny have also published similar experiences. The symptoms observed by the various authors were either gastric, intestinal or pelvic. The impression was always that there was some obstacle in the intestine and that painful distention took place above the obstacle. Medication was always unsuccessful. These cases frequently simulate chronic constipation, enteroptosis and pelvic neuralgia. Sometimes they were, as the autopsy table showed, taken for ulcer or carcinoma of the stomach, or cholelithiasis.

The principles observed by Mayo in his *pylorectomies* are also noteworthy. Of his 41 cases, 37 were performed for carcinoma and four for inveterate ulcer. His steps are the following: "After opening the abdomen doubly ligate and divide the gastric artery, then ligate and divide the necessary amount of gastrohepatic omentum close to the liver, leaving most of its structure attached to the stomach. Doubly ligate and divide the superior pyloric artery and free the upper inch or more of the duodenum. Then with the fingers as a guide underneath the pylorus, in the lesser cavity of the peritoneum, ligate the right gastro-epiploic or gastroduodenal artery, and progressively tie and cut away the gastrocolic omentum distal to the glands and vessels up to the appropriate point on the greater curvature, and here ligate the left gastro-epiploic vessels. Then double-clamp the duodenum purse-string, divide between with the cautery, leaving one-fourth inch projection. With a running suture of catgut through the seared end the duodenum is closed as the clamp is removed, a purse-string suture about the duodenum enables the stump to be inverted. The proximal end of the stomach is double-clamped along the Mikulicz-Hartmann line and divided with the cautery, leaving one-fourth inch projection. Suture through the seared stump with a catgut button-hole suture. This is again turned in after removal of the clamp by a continuous silk or Cushing suture. Finally follows independent gastrojejunostomy."

The value of *subcutaneous feeding* in such disturbances of the gastro-intestinal tract, in which nutrition by mouth or rectum has become impossible or is contraindicated, is proved by Friedrich, who injects 40 to 100 grams of grape-sugar in a three per cent. solution *per diem*. Recently he also tried the pure pepsin-peptone, free from albumoses. A useful combination consists of two grams of grape-sugar, two grams of table-salt and four grams of pepsin-peptone to 100 grams of water. Especially in very severe disorders, like perforation of the stomach or intestine or severe peritonitis subcutaneous feeding is apt to tide the patient over the critical period. (Ref.—Can verify the correctness of this statement by his own clinical experience.)

Similar good results were obtained by Credé in using a meat preparation which contains soluble albumin in a readily assimilated form, 95 per cent., and traces of iron and salt, two per cent. This preparation, called kalodol by him, resembles the albumin in the circulation. This explains why it is so easily assimilated. About four kalodol injections *per diem* suffice for a patient. Rectal injection of kalodol may also be resorted to, as it is easily absorbed.

Chaput is in favor of performing capital operations on the abdomen under local *cocaine anesthesia*. He resorts to general anesthesia only when the patient is timid. He performed gastro-enterotomies, appendectomies and hysterectomies, under cocaine anesthesia.

To intensify the resistance of the peritoneum against infection, von Mikulicz advises the internal administration of acid of *nuclein*, which is supposed to increase the number of the leucocytes, thus rendering bacteria innocuous.

Fig. 2.

Metastatic nodules of thorax, abdomen, face and arms.

In *suppurative peritonitis* Küster places the patient in the abdominal position, in order to facilitate the discharge of the exudate from the area of operation.

Kapsammer's observation, that the *freezing point* of the *urine* may be influenced by reflex polyuria from catheterization of the ureters, is noteworthy. The results of this new method should, therefore, be taken *cum grano salis*. In one of his cases of renal tuberculosis, for instance, there was five per 1,000 albumin, and the freezing point of the urine was 52° C., while that of the blood was 58° C. Despite this fact

nephrectomy was performed, the albumin disappeared and the patient recovered. Kapsammer pleads for catheterizing both ureters in order to arrive at a correct diagnosis, and is also in favor of employing the phloridzin and methylene blue functional tests as well. One case of tuberculosis of the bladder was cured by the local use of bichloride of mercury in combination with guaiacol-iodoform. In bilateral tuberculosis it is often found that a slightly affected kidney recuperates after the removal of the diseased mate.

On the basis of 79 cases of osteomyelitis and 108 osseous tuberculosis, von Mostig-Moorhof recommends *filling* up *osseous cavities* with *iodo-*

Fig. 3.

Metastatic nodules in the back, face and arms.

form. In some cases of osteomyelitis of the tibia he removed the tibia in its entirety and filled the resulting defect with his "Iodoform-plombierung." As is well known, iodoform is not absorbed by dead bone, but only when it is reached by the new growth of osseous tissue. Thus absorption of the iodoform takes place so slowly that the danger of intoxication is small. The process of healing can be studied by skiagraphy.

While many interesting experiments have been made on the *carcinoma* question, nothing new has been derived from them. Doyen claims to have isolated a bacterium, which he calls the *Micrococcus neoformans.* He obtained vaccines and toxins from it. He has treated 126 cases so far, 21 being cured and 47 improved. In 58 patients there was a negative result. Eight months of cultivation are necessary for the production of an effective toxin. So far Doyen's observations were not corroborated by other investigators.

The observation that epithelioma may be produced by continued exposure to the Roentgen rays is not in favor of bacterial origin, but of the irritation-theory (Ref.).

Literature upon the application of the *Roentgen rays* in surgery has increased remarkably. The representation of renal calculi has become a reliable method in the hands of the expert. Reports on the successful skiagraphy of biliary calculi have also become more frequent. The therapy of fractures is much simplified and perfected since the Roentgen guide shows the true nature of the conditions. Irreducible fractures are now operated upon early instead of waiting for the development of a conspicuous deformity, which at a late stage cannot be corrected as well as at any early period of the injury.

The knowledge of the various diseases of the bones has been much augmented, and new laws of differentiation between inflammatory, syphilitic, tuberculous or osteomyelitic processes, and osteoma, osteosarcoma and osseous cysts have been established.

The indications for the therapeutic utilization of the Roentgen rays have become clearer and great efforts are made to keep facts and conjectures well apart. While there are many encouraging results reported in some malignant diseases, utopistic views should not be held, and it must always be kept in mind that this new and delicate field is still in a stage of development. The *radium* has become a competitor of the Roentgen rays in this respect, but, while it has some advantages over the Roentgen rays, as a whole, it has so far proven to be of limited practical importance. Its undoubted advantage over the Roentgen rays is, that it can be placed into mucous cavities, like the nose, esophagus, stomach, uterus, urethra, etc. The small size of the radium tubes also permits of imbedding them within the tumorous tissue through an opening made by puncture.

The radium treatment may also be tried in cases in which the Roentgen ray treatment has proved to be unsuccessful. As a diagnostic means the radium in its present form cannot be used in practice.

The *Finsen method,* ingenious as it is, can, in its present state, not compete with the Roentgen treatment. It should, therefore, be resorted to in cases only in which the Roentgen ray or radium treatment has proved to be unsuccessful.

A variety of new and useful apparatus were invented, among them the compression-diaphragm, the various skiameters, the osteoscope, and the non-penetrable glass apparatus of Kohl, which shield the operator, may be mentioned.

What may sometimes be done with the Roentgen rays is illustrated by this lady (demonstration) who was presented in this room two years ago, shortly after operation. She showed the first signs of sarcoma of the orbit nearly three

years ago. Enucleation of the eyeball was undertaken, but recurrence in the frontal bone took place three months thereafter, and finally reached such an extent that it was regarded inoperable.

After having ascertained the extent of the growth by skiagraphic exposure, I removed the diseased bone portions. Three weeks thereafter, when cicatrization had taken place, irradiation was begun three times a week, exposing the patient ten minutes each time. No change was observed during two month's treatment. But when irradiation was stopped for three weeks, the signs of recurrence again appeared, the vicinity of the orbit projecting far. Now Roentgen irritation was resorted to every day at small distance, low vacuum and high current being chosen. After eleven exposures extensive dermatitis developed, which proved to be of the ulcerative type, within the center of the irradiated area. At the same time complete alopecia of the diseased side set in. The patient suffered considerably for a week, then the symptoms gradually subsided. The treatment first consisted in the application of Burow's solution, and in the use of xeroform gauze later. Three weeks after the beginning of the vehement dermatitis all signs of the sarcomatous infiltration had disappeared, especially the projection, and the general condition of the patient improved remarkably. With few intermissions light Roentgen treatment (twice a week) was kept up until to-day, that is, two years after the operation. There is still a slight projection in the orbital region, which, however, appears to be composed of normal tissue. It is interesting to note that the scar produced by the incision, has completely disappeared after the dermatitis. So, instead of disfiguring the patient, the burn has in this instance served as a beautifying agent. Whether or not a recurrence will take place in this case cannot be determined; still, after the lapse of two years this does not seem to be probable. The general condition of the patient is undisturbed. Of course we must not generalize from one case. There are cases of sarcoma in which the Roentgen rays show no inhibitory action at all, while others of the same variety react at once and markedly.

Clinical experience indicates that the results in round-cell sarcoma are better than in the other types. Other factors are to be considered, too; for instance, the general composition of the growth and the region. My experience shows a larger percentage of improvements in sarcomas of the face than of the extremities.

Of course, whatever can be reached by the surgical scalpel should not be left to the rays, the latter to be employed largely after operation or in inoperable cases.

As a counterpart of the favorable case just demonstrated, this case of a man, aged fifty-eight years, may serve. His history reveals that two years ago he noticed a hard swelling above the right gastrocnemius muscle, which was painless at first; but after having slowly increased in size, there was considerable discomfort while walking.

A year ago I made an extensive extirpation of the growth, which at this time had reached the size of a man's fist, at the Post-Graduate Hospital, removing a considerable portion of the gastrocnemius muscle at the same time. Three weeks afterward Roentgen treatment was begun, but the patient became negligent until four months after the operation a recurrence formed in the scar (Fig. 1).

Irradiation was taken up then for a short period, during which about a hundred metastatic nodules formed on his trunk, face and extremities (Figs. 2 and 3).

Microscopical examination, made by Dr. Henry T. Brooks, showed the presence of round cells. The patient begins to present the signs of cachexia now. He is taking Fowlers' solution, but nothing seems to arrest the metastatic process.

THE INFLUENCE OF THE FIRST AND SECOND DENTITION PERIODS IN THE ETIOLOGY OF EPILEPSY.[1]

BY WILLIAM P. SPRATLING, M.D.,
OF SONYEA, N. Y.;
MEDICAL SUPERINTENDENT OF THE CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y.

It is my conviction that we are never justified in looking upon the convulsions of infancy and early life as harmless manifestations.

Numerous convulsions appear at this period that begin as benign and end as such. But thousands begin as benign that end in established epilepsy. The fact that many infantile convulsions do not pass into epilepsy grants us no license for regarding such convulsions as innocent of future harm.

I am led to make this statement after ten years' experience at The Craig Colony for Epileptics, during which time it has been my privilege to study the etiology of epilepsy in nearly 2,000 cases.

It would be tedious to attempt to recount the times I have questioned the parents of epileptic children and studied in conjunction with the information thus derived the medical testimony in the case along this line.

Parents very commonly answer questions concerning the probable cause of the disease in their child, and the age at which the first convulsion appeared in this way: "Yes, my child had convulsions as a baby. They came on before the end of the first year. I was told that they were 'teething fits' or 'worm' fits or 'stomach' fits, and that they would go away of themselves after a while."

To a certain extent such prophecies are true. Convulsions that appear in connection with the

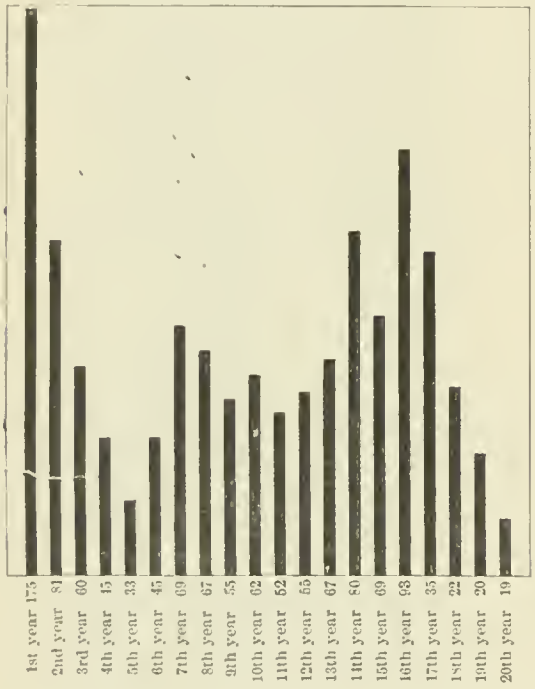
[1] Read before the Section on Pediatrics, New York Academy of Medicine, October 13, 1904.

first and second dentition do often disappear entirely for years, only to recur at some future time when the child is passing through a period of physiologic stress, particularly like the stress of the epoch of puberty.

The lesson we often fail to learn is *the necessity for constantly recognizing in such children the presence of the convulsive tendency.* To keep the child free from convulsions in the future, this tendency must be borne in mind and always respected.

The question I particularly desire to discuss before you to-night is whether difficult dentition alone or acting in conjunction with a previously prepared organism is capable of causing convulsions that may pass into epilepsy.

Chart 1.



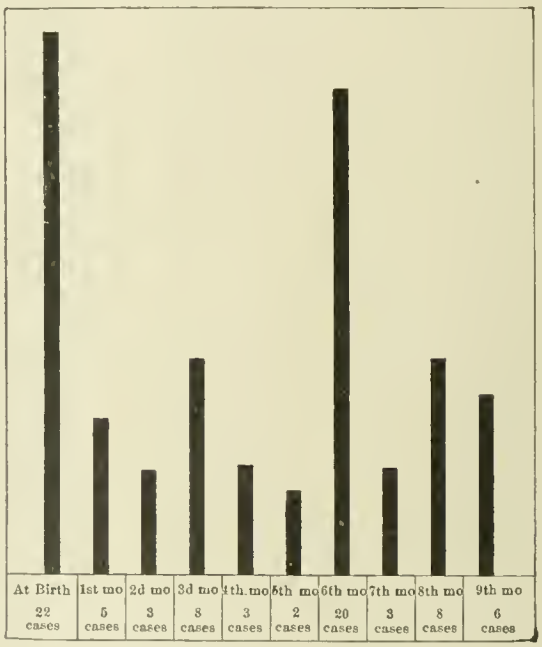
Showing the age in years at which epilepsy originated in 1,215 cases. Note the rise during the six, seven and eight years, coincident with the second dentition period.

The evil effects of dentition when it departs from physiologic lines, apparently do not now have the recognition that was given them some years ago. Many physicians of the present day deny *in toto* that "teething" ever causes convulsions that may pass into epilepsy. From this view I dissent. I have long felt that in selected cases the "stress" of difficult dentition is the touch-stone in the causation of convulsions. Unfortunately, few epileptic children are placed in colonies or institutions especially designed for them until they are confirmed epileptics. This fact denies to investigators in such institutions the opportunity of studying the incipient stages of epilepsy.

For some years I have been studying the age at the onset of epilepsy in several thousand cases, to determinate what proportion of them acquired epilepsy coincident with the first or second dentition periods. The results of these studies so impressed me with the undoubted influence of such periods in causing, or helping to cause, this disease *in selected cases,* that I am pleased to lay the main facts that I have ascertained before you, hoping that your experience and discussion may throw more light on a problem about which there is now much obscurity.

I show you first Chart No. 1, that gives the age for each year at the onset of epilepsy in 1,215 cases from the first to twentieth years inclusive. These 1,215 cases, all under twenty years of age, represent 80 per cent. of all patients admitted

Chart 2.—First Dentition.



Showing the age in months at which epilepsy originated in 80 cases. Note the increase at the sixth month, which marks the beginning of the influence of the first dentition, that is, the period when the teeth begin to cut through the gums.

to The Craig Colony up to the time these figures were made.

The next point to which I call your attention is the large number of cases during the first year of life—175, equal to more than 14 per cent. of them all.

After passing the first year there is a very decided and continuous decline up to and through the fifth year, there being 33 cases only in that year, or about one fifth as many as during the first year.

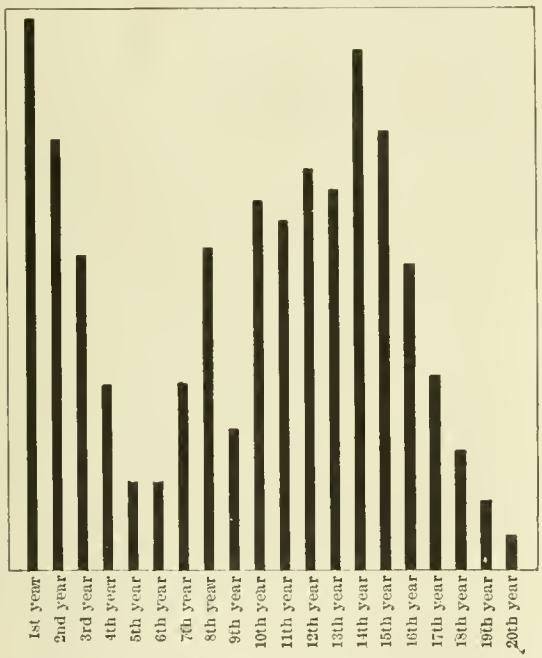
After leaving the fifth year we enter upon the period of the second dentition, and we are struck at once with the decided rise in the number of cases during the sixth, seventh and eighth years: 45, 69 and 67, respectively, the number dropping to 55 during the ninth year.

The remainder of Chart 1, while of great interest in showing the very marked influence of the epoch of puberty in both sexes in causing epilepsy, is of no particular interest in our present studies; except, I will repeat the important fact that so-called "teething convulsions" which disappear early are quite apt to recur under the stress of the twelfth to sixteenth year period.

Now we will return to the first year which embraces the first dentition period, and note the number of cases arising each month from birth up to and including the tenth month.

Chart No. 2 shows this in 80 out of the 175 cases mentioned in the first year of Chart 1. In the remaining 95 cases, the exact month of origin being in some doubt, they were not considered.

Chart 3.



Showing the age in years at which epilepsy developed in 3,523 cases. Note the greatest number during the first year, the increase during the seventh and eighth years, and the still greater increase during the epoch of puberty.

The first column in Chart 2 shows that epilepsy was present in 22 out of 80 cases, or 27½ per cent. of them all "at birth;" the second month shows a decline to five, the decline continuing through the third month when three cases only occurred. A notable increase takes place during the fourth month, followed by a second decline through the fifth and sixth, after which a very positive rise is noted during the seventh month. 20 cases in all occurring during that month—equal to 25 per cent. of the entire number.

The fact of importance about the rise during the seventh month is that it marks the beginning of the influence of the first dentition period, *i.e.*, the period when the tooth usually begins to cut through the gums.

Chart 3 is made from a grand total of 3,523 cases in all of whom epilepsy developed before the twentieth year; these 3,523 cases constituting about 80 per cent. of the 4,358 studied preliminary to making up this table.

Here the greatest number for one single year was 376 and was during the first year.

All these, in brief, may be ascribed to congenital causes, to heredity, to birth accidents, and to the first dentition. Passing the first year a continuous decrease is noted through the second, third, fourth, fifth and sixth years, when 127 cases only out of 3,523 occurred. Here again the seventh year shows an increase to 168, this increase continuing through the eighth year and reaching 174. After this a fluctuating rate is noted until the twelfth year when the stress of puberty begins to be felt. The four years that cover this developmental period show a vast increase in the number of cases—a grand total of 877 out of 3,523 occurring during these four years.

The fourteenth year which marks the acme of the influence of the period of puberty, stands second in the number of cases for one year periods, there being 258 cases in that year as compared to 376 during the first year. Passing the epoch of puberty the decline is sharp and continuous; so much so that by the time the twentieth year is reached, the time has passed during which more than eight-tenths of all cases of epilepsy occur.

Before citing specific cases that illustrate the influence of the dentition periods in causing epilepsy, I will give the opinions of some leading neurologists on the point in question.

Gowers says: "It is convenient to group the infantile causes of epilepsy into three classes: First, those in which labor was protracted and difficult, or (seldom) premature and swift, in which the symptoms, immediately after birth, suggest some meningeal hemorrhage. Second, cases in which the attacks begin by a severe fit or series of fits, with indications of a local cerebral lesion. Third, cases (which constitute the majority) in which the infantile fits are at first slight and are associated with retracted development, especially manifested by backward teething. The largest group is the third,—the cases in which epilepsy dates from the convulsions called "teething fits." In about two-thirds of the cases beginning in infancy, particulars of which could be ascertained, the fits arose from such so-called "dentition convulsions." It seems legitimate to ascribe to the same cause a similar proportion of the cases respecting which no information was forthcoming. If so, we have a total number of cases due to this cause which constitutes 7 per cent. of all the cases investigated."

Voisin states, "Epilepsy is especially a disease of infancy and of the young. It may come at birth, but usually it is at the time of dentition that the first manifestions occur. In these cases dentition is the touch-stone of hereditary predis-

position. Then at the age of seven or eight the attacks recur with the second dentition.

Feré says: "Epilepsy may appear in connection with dental disturbance. The frequency of convulsions in young infants during dentition is well known."

Graeme M. Hammond says: "I have records of several cases in which convulsions, due to dentition, were followed by true epileptic convulsions."

Peterson says: "I recall a number of cases in which epilepsy was due to the convulsions of dentition."

Clouston says: "I have seen the convulsions of dentition followed by prolonged delirium, ending in idiocy, or in true epilepsy, or insanity of adolescence."

Jacobi says: "Every convulsion ever so slight may produce cerebral hemorrhage with all its possible results,—epilepsy, idiocy, paralysis, and insanity."

Dr. Jacobi, in this connection, apparently did not mean that the convulsions referred to were due to dentition.[1] He did admit, however, that the spasms and convulsions of infancy are serious manifestations, and if allowed to go unchecked may lead to explosions of genuine epilepsy, and later on to insanity.

In reviewing the etiology of convulsions in children, Sachs[2] has this to say: "Of the influence of two conditions there can be no reasonable doubt. The first of these is dentition; the second, gastro-intestinal irritation. There has been some question whether a tooth about to cut through the gum can cause a decided eclamptic seizure.

Delayed dentition is so frequently associated with rickets that the latter condition is considered by many to be the chief factor, and this I believe to be true; but convulsions do at times occur in children who present no tangible signs of rickets. Moreover there is good reason why a cutting tooth should produce convulsions in a child so disposed, say by rickets, or any form of exhausting disease. "The cutting tooth" is a direct irritant to the filaments of the trigeminal nerve, which carried this irritation easily enough to the convulsive centers at the base of the brain. I have little doubt of this special reflex origin of convulsive seizures since observing in the adult the occurrence of severe epileptic paroxysms in a case of trigeminal neuralgia.

I could easily bring scores of cases to your attention in which epilepsy followed convulsions that appeared for the first time coincident with the first dentition, but I will report three or four only.

Case I.[3]—At five months of age a little girl had a severe attack of enteritis that lasted a week, and was attended by "several severe convulsive seizures in every respect like those met with at this age in similar conditions." After recovering from the enteritis she had no further trouble until the first tooth was cut at the seventeenth month, when "she began having convulsive seizures very frequently, often several in a day. Anger or freight always acted as the immediate excitants of attacks. At such times she held her breath until she became very much congested about the face and chest, when the seizures would begin,—first as tonic, then as clonic spasms, and lasted about three minutes, consciousness being entirely lost, and post-convulsive stupor lasting for several hours."

When the case came to my knowledge there had been no attacks for a year, the father stating, "Troubles that would have brought on a convulsion a year ago, seem now to have no unusual effect on her."

This case is quite typical of its kind. In the absence of any unfavorable heredity, this little girl may have no further seizures. Nevertheless, she should be watched with the utmost care during the second dentition, or during the eruptive fevers, should she have any of them, and especially should be watched during the critical epoch of puberty. Had the first convulsion from which she suffered caused a cerebral hemorrhage, as it might readily have done, she would unquestionably have become a hemiplegic epileptic; and furthermore, had she not been obliged to run the gauntlet of the iritation incident to the first dentition, which, owing to a developmental fault, was delayed, it is not likely that she would have had any convulsions after the attack of enteritis had subsided.

It is clear that the irruption of teeth in this case incited the second series of attacks.

Case II.—G. F. (female). Admitted to the Craig Colony in May, 1904; family history bad; mother had "spasms" when a child, and "periodic headaches throughout her life,"—the "spasms" occurring at the first dentition. Father alcoholic. Patient's birth was normal in every respect. No illness of any kind up to the sixth month when *the first convulsion appeared coincident with the cutting of the first tooth.* The second convulsion followed a week later, after which they regularly appeared at the rate of two to four a month. At first they were petit mal, but later changed to grand mal; invariably affecting the right side more than the left.

At the age of seventeen years she is a confirmed epileptic with attacks that average ten a month. Her mental condition is greatly impaired. She is subject to violent outbursts of temper, and occasionally commits unpremeditated assaults upon those about her. All her attacks grand mal, and all are severe.

In this case there is no room to doubt the establishment of genuine epilepsy as a result of convulsions incited in the first instance by dentition.

Case III.—W. A. W. (male). Admitted to the Craig Colony June 7, 1904; epilepsy then of

1 "Causes of Epilepsy in the Young," Medical News, December 13, 1902.

2 Nervous Diseases of Children, 1895.

3 This case was reported to me by Dr. W. L. C., the patient being a member of his family.

eighteen years' duration. Family history unsatisfactory. Father a marked inebriate for twenty years. Patient had no convulsions at birth. Was well developed and healthy in every respect up to the ninth month when the first "spasm" appeared, coincident with the cutting of the first tooth, several occurring in quick succession, and all being severe. Two weeks later they recurred, when they caused a cerebral hemorrhage which resulted in left hemiplegia. Attacks from the first of the grand mal type. Mental condition characteristic of true epilepsy. Eighteen years after onset of the "spasms" in this case, epileptic attacks regularly occurred at the rate of four to ten a month. In this case it is equally as clear that the apparently harmless "spasms" or "convulsions" due to the first dentition later on caused essential epilepsy.

Case IV.—P. A. K. (male). Admitted to the Craig Colony when twenty-one years of age; epileptic since the eighth month. Family history bad. Father a habitual drunkard. Nine children in the family. Six of them had "teething convulsions," one girl dying at the ninth month while in such "spasms." Patient's birth normal. No trouble until the eighth month when first convulsion appeared with "the first set of teeth he cut." This convulsion was severe, lasting twenty minutes. At four years of age he had "a convulsion that lasted forty-eight hours," and which was followed by "paralysis so that he crept for a year before he could again walk." His palsy is still marked seventeen years after its onset, while his attacks of grand mal that appear daily are extremely severe.

Cases V and VI.—I. J. and A. J., sisters, members of an epileptic family. Paternal grandfather and father had epilepsy, the disease appearing in the latter when he was twenty-six years of age, the immediate exciting cause being alcoholism. The father inherited a predisposition to epilepsy, and might have escaped the disease had he carefully guarded his epileptic tendency; but his habits brought it to light.

The two patients, in question, inherited epilepsy from the father, or at least so strong a tendency to it that the slightest irritant was all that was required to bring it into full development. The elder daughter reached the twelfth month when she began having "teething spasms." She had been perfectly well to that time. The younger daughter passed through an almost identical experience. She weighed eight pounds at birth, was well developed and normal in every respect. She also had "teething spasms" at the twelfth month, and from these naturally passed into a true epileptic. I say she naturally did this, because under such an unsatisfactory heredity, and the etiologic factor in question, no other outcome was to be expected.

The father and two daughters were admitted to the Craig Colony in August, 1904; one daughter being fourteen, the other eleven years of age; both having severe grand mal attacks on an average of one to three times in twenty-four hours. All of them bear marked evidences of the stigmata of epilepsy.

It is always a mistake, in my opinion, to regard the convulsion of dentition, or the convulsions due to any other cause in early life, in any other than a serious light. They are never positively benign, at least we have no right to regard them so. That infants who have convulsions escape serious consequences in the future is always a matter for congratulation; but the physician should never assume that this is the outcome to be expected. When disease tendencies are so strongly marked as these morbid manifestations so plainly indicate, the most constant care and treatment should be undertaken at once in every case with a view to preventing epilepsy, or idiocy, or insanity, or other states of degeneracy destined to destroy the mental life of the individual in question.

In conclusion, my views in the matter may be briefly summarized as follows:

1. Difficult dentition, *i.e.*, the piercing of the gums by the tooth may, in suitable subjects, constitute a sufficient irritant to cause convulsions.

2. In suitable subjects these convulsions may ultimately lead to epilepsy.

3. By suitable subjects I mean infants who inherited a neuropathic tendency to disease; whose parents had epilepsy, or insanity, or who were alcoholic, or suffered from some other general vice that could be transmitted to the offspring in some form capable of vitiating its powers of resistance to disease.

4. I do not believe that difficult dentition alone in a child who inherited no ancestral taints, and who at its birth is free from a tendency to nervous disease, can cause epilepsy.

5. Great caution must always be exercised to lay the true cause in cases of this kind where it belongs; for the reason that gastro-intestinal disorders, the sequelæ of the eruptive fevers and other factors common at this age, may produce similar results.

THE CARE OF FRACTURES FROM THE STANDPOINT OF THE GENERAL PRACTITIONER.

BY WM. S. NEWCOMET, M.D.,

OF PHILADELPHIA;

PHYSICIAN IN CHARGE OF X-RAY LABORATORY, PRESBYTERIAN HOSPITAL; REGISTRAR TO ST. AGNES HOSPITAL, ETC.

ALTHOUGH this subject might seem to have been worn threadbare, the indulgence of this assembly is asked while their attention is drawn to several instances where obscure fractures have caused considerable annoyance to the attendant physician as well as to the patient, and in a few instances the present existence of both would have been far more pleasant if the difficulty had been properly recognized and treated.

Of all the trials that come within the scope of a physician's labor, it can safely be said that fractures cause him the most trouble. These injuries often appear to be trivial, but as time

passes and the patient is still annoyed either by pain or loss of function, friends persuade him to seek another practitioner and he often receives some indiscreet advice, and in the end such cases usually lead to the courts. This situation is most embarrassing, and while the law only expects the physician to do his duty, it is the jury that in most instances is called upon to decide whether he has done it. At such a trial, just as the case was given to the jury, a lawyer who was defending a physician once said he knew the case was won "if there was not a man on the jury who owed a doctor bill."

Although such occasions are rare, the liability of such occurrences would be decidedly less, if in cases of fracture the proper precaution was always taken.

The older text-books advise the administration of an anesthetic in all injuries the nature of which is the least obscure, but this method has been superseded by the X-ray, which is safer and far more reliable, giving a graphic description of the exact amount of damage.

It would seem improbable that such injuries as fracture of the femur and dislocation of the shoulder would lead to error, yet in the last year two of the former and three of the latter have been seen and in all but one of these cases the deformity will be permanent.

A less disastrous mistake, and one that often happens, is the neglect to recognize a green-stick fracture. Such an error, however, is not likely to lead to any serious consequences, though the patient is made more comfortable when the proper dressings have been applied. A most troublesome class of fractures occur about the joints, commonly at the wrist, elbow, shoulder or ankle. In these cases only a small fragment of bone is torn off and is often bound so firmly by the ligaments that the ordinary signs of fracture are absent, thus concealing the true nature of the injury. These injuries are often treated as sprains, and when the thickened process is noted after the acute swelling subsides, it is supposed to be due to inflammatory débris. In institutions where all such injuries are systematically examined by the X-ray, this fact has been substantiated. Such injuries will cause more inconvenience to the patient, owing to the involvement of the joint, than do fractures of the shaft of the long bones with considerable displacement.

A demonstration of these facts is well illustrated in the following series:

In the case of Mrs. S., where the posterior portion of the radius was broken off, although a fracture was suspected, the signs were quite obscure. This might have been on account of the swelling, although it was more likely to be due to the firm ligaments. It can easily be seen how a good radiograph, in such an instance, would be more satisfactory than the examination of the part under the influence of an anesthetic. The amount of displacement of the fragment can easily be seen in the radiograph made shortly after the injury, which gives a clear conception as to the exact amount of damage. In the second series of radiographs, made several months after the injury, very little evidence of the original displacement remains, although at this time the patient still suffered considerable inconvenience from pain and loss of function.

It is interesting to compare this group of radiographs with those of Miss J., where the fracture of the radius was transverse and about three-quarters of an inch above the wrist-joint. If it were not for the fact that the styloid process of the ulna was also broken off, except on close inspection the injuries would appear to be the same, although the last case had the deformity typical to such an injury.

Another radiograph shows a rather unusual injury, occurring in the case of Master X., where the fracture existed just below the epiphyseal cartilage and, like the first case, was very annoying both from the standpoint of diagnosis and treatment.

Just here it would be well to call attention to the difficulty experienced in correctly interpreting radiographs of children when the injury exists in the neighborhood of the joints. It is a good rule, where it is possible, always to take the sound counterpart in exactly the same position and compare the relations in the two pictures.

In the foregoing cases it is easily seen how two of them could have been mistaken for sprains, althought he severity of the symptoms might attract attention for further investigation. On the other hand, a fracture, such as occurred in the case of Mr. S., would be entirely overlooked; in this instance the man suffered very little inconvenience, either at the time of injury or during treatment.

It is interesting to compare the last two radiographs with the series of the first case, where so far as can be seen, the result is perfect, although at that time it will be remembered the patient still suffered considerable inconvenience; in this last group there is evidence of considerable thickening of the bone, while the patient suffered very little pain.

The annoyance that results from fracture cases in most instances may be attributed to a faulty conception of the location and extent of the injury, although at times the failure to obtain good results might be due to the treatment. In two instances that were lately seen, ugly deformities were due to a method of dressing which may be good in theory, but very bad in practice; namely, after the bone is placed in position or "set" the dressings are applied, and then they are allowed to remain on for three or four weeks; if in that time they become loosened, as they sometimes will from the subsidence of the acute swelling, a new bandage is simply wrapped around the old dressings. This is an extremely dangerous procedure and one that should be condemned, as it will always give a poor result.

In conclusion, it might be stated that too much care cannot be given to our fracture cases, and where doubt exists as to the nature of the injury, it is best to clear up the mystery immediately and not wait until the bones become united and leave a deformity that lasts the remainder of the patient's life. It is not always possible to obtain results that are most desired, but these unfortunate instances would not be so common if in all cases the proper precautions were taken.

A NEW METHOD FOR STAINING THE CAPSULES OF BACTERIA: PRELIMINARY COMMUNICATION.

BY LEO BUERGER, M.D.,

OF NEW YORK;

PATHOLOGICAL INTERNE, MOUNT SINAI HOSPITAL, NEW YORK.

ALTHOUGH many methods for staining the capsules of bacteria have been devised, the opinion seems to be almost unanimous that they are for the most part very variable and unreliable in their results. Not this alone, but also the difficulty of differntiating the encapsulated Diplococcus from similar lanceolate organisms, especially of the streptococcus type, led the writer, early in May of this year, to devise a procedure which would enable the bacteriologist to identify the *Diplococcus lanceolatus* with greater ease and precision.

The recognition of the encapsulated organisms in the very first cultures taken from exudates, when for any reason their demonstration in the exudates themselves is impossible, is of prime importance. It is in this particular regard that the method advocated fills a want left by the older procedures.

By it capsules can be obtained not only in exudates but also on certain culture media. The configuration of the capsule of the pneumococcus, when recently isolated, and on certain media, differs from that produced by the methods employed heretofore, and from that of other organisms in so characteristic a manner that the diagnosis of the organism becomes a comparatively easy matter.

The older stains present the capsule as a diffusely staining, poorly outlined, elliptical band immediately surrounding the diplococcus. With my method it has the following features: There is a refractile, deeply staining, regularly outlined, narrow, elliptical capsule membrane, separated from the diplococcus by a clear area of capsular substance which either remains unstained or takes a faint color. Each of the other encapsulated organisms thus far studied has its own peculiar type of capsule. The *Bacillus mucosus capsulatus* shows a broad mucoid envelope with an easily destructible membrane, the *"Streptococcus mucosus,"* one of similar nature, and some strains of the pyogenic streptococcus shows only a fine linear envelope.

The Method.—The necessary solutions are as follows: (1) Müllers fluid (bichromate of potassium, 2.5 grams; sulphate of sodium, 1.0 gram; water, 100 c.c.) saturated with bichloride of mercury (ordinarily about 5 per cent). (2) Beef, human or other blood serum diluted with an equal amount of normal salt solution; or ascitic or pleural fluid. (3) 80 to 95 per cent. alcohol. (4) Tincture of iodine, U.S.P. (5) Freshly prepared stain; anilin water gentian violet, made up as follows: Anilin oil 10, water 100, shake, filter and add 5 c.c. saturated alcoholic solution of gentian violet; or, 10 per cent. watery fuchsin (*i.e.*, saturated alcoholic solution of fuchsin, 10.0, water 100.0). (6) Two per cent. watery salt solution.

Technic.—The culture is thinly and carefully spread over a perfectly clean cover-slip by means of a drop of diluted serum.[1] Just as the edges begin to dry the fixing fluid, solution No. 1, is poured on, the cover gently warmed over the flame for about three seconds, rapidly washed in water, flushed once with alcohol, and then treated with iodine for one to two minutes. The iodine is in turn thoroughly washed off with alcohol, and the specimen dried in the air. Staining for two to five seconds, and washing with salt solution completes the procedure. The specimen is mounted in the salt solution and ringed with vaselin.

Sputum and pus can be stained in a similar manner, the addition of serum being unnecessary, except in very mucoid, stringy purulent exudates.

The method depends therefore upon the rapid fixation of the bacteria while still alive and when spread in a medium which prevents dissolution of their capsules. The Müller's fluid, saturated with bichloride of mercury (*i.e.*, Zenker minus acetic acid), which is found ready in every laboratory, has given the best results. However, a simple saturated solution of bichloride of mercury in one-half per cent. salt solution has also been tried, but hitherto has given less distinct pictures. The results obtained by the use of other fixatives will be reported on at a later date.

Thin spreads can be obtained by first emulsifying the culture in a drop of serum on a separate slide. It is of importance to thoroughly rid the specimen of iodine. The preliminary alcohol wash before the iodine steep is not absolutely essential. The whole procedure, taking some two minutes, can be much shortened by reducing the action of the iodine to thirty seconds. This is accomplished by flushing several times with fresh iodine. Thus a good preparation can be finished in about one minute.

As for the stain, watery fuchsin also gives good results. Double staining by means of gentian-violet and fuchsin is also feasible. Good permanent balsam mounts can be made from these double stained specimens. Methods for making all mounts permanent are now nearing completion and will be given in detail in a future publication.

The questions of the occurrence and variation

1 Hiss: Centralblatt für Bact., etc., 1902, XXXI, p. 302.

of the capsules of different organisms on artificial media, of changes in morphology, and of the differential diagnosis between the pneumococcus and streptococcus by means of this new technic. I will reserve for discussion in a future paper. The results obtained warrant us in recommending the method to the consideration of the bacteriologist and clinical microscopist.

A NEW CASE OF CHLOROMA WITH LEUCEMIA, WITH A STUDY OF CASES REPORTED SINCE 1893.

BY GEORGE DOCK, M.D.,
AND
ALDRED SCOTT WARTHIN, M.D.,
OF ANN ARBOR, MICH.

(Continued from Page 1084.)

Marrow from Tibia.—Sections show a fatty marrow containing small, irregular islands of tissue exactly like that of the sternal and vertebral marrow, consisting of cells of the "large lymphocyte" type with a high proportion of mononuclear eosinophile cells of varying size and shape. In such islands the normal marrow tissue is entirely replaced. They contain but few red blood cells, and nucleated red cells are extremely rare. From these islands irregular cords of similar cells extend onward through the distended capillaries and blood spaces between the fat cells, the cords becoming smaller as the distance from the main island increases. The appearance is that of a growth extending from the center out into the neighboring tissue through the blood and lymph spaces. This growth is not at all uniform and in many of the capillaries between the fat cells the dilated lumen may be packed with red cells, few cells of the lymphocyte type being present. In such blood spaces nucleated red cells are occasionally seen, and a few bone-marrow giant cells are also found. Neutrophile myelocytes are also more common than elsewhere. Portions of the fatty marrow appear fairly normal with small collections of apparently normal red marrow, but even here the prevailing type of cell is the large lymphocyte. Eosinophiles are not so numerous in these areas.

Smears of the marrow from the tibia show more red blood cells and fewer eosinophiles than the smears of the sternal or vertebral marrow. The red cells are pale and show a greater or less irregularity of size and shape. Nucleated reds are less rare. The prevailing type of cell is, however, the "large lymphocyte." Few of these have any protoplasm, and the majority of the nuclei contain vacuoles. The background contains many free eosinophile granules.

Spleen.—Sections show a diffuse hyperplasia, both cellular and reticular. The distance between the trabeculæ is increased. The follicles are almost entirely absent, being represented only by scattered small collections of lymphoid cells around some of the small arteries and the trabeculæ. The increase in the fine reticulum of the pulp is well marked; the blood spaces are obliterated or contain few or no red cells. The spaces of the reticulum are filled with cells that are chiefly of the large lymphocyte type, a very large proportion being eosinophiles. In many fields the number of esoinophiles is greater than the non-eosinophiles. Many neutrophile myeloctyes are also present, and the number of polymorphonuclears and small lymphocytes is greater than in the bone-marrow. On the whole, the pulp presents a distinctly myeloid character except for the absence of red cells and giant cells. The small follicles are made up almost wholly of small lymphocytes and contain very few cosinophiles or none at all. There is no infiltration of eosinophiles or of other cells in the connective tissue of the trabeculæ; as a rule, the cosinophiles stop sharply around the border of both follicles and trabeculæ. A very striking feature of the sections of the spleen is the fact that while the splenic arteries are empty, or contain many cells of the large lymphocyte type, the veins are distended with red blood cells with a relatively small number of white cells. Of the latter the polymorphonuclears and cells of the lymphocyte type are in preponderance.

Lymph Glands.—In general the sections of the lymph glands present a cellular hyperplasia, large numbers of cells of the "large lymphocyte" type infiltrating the lymphoid tissue and replacing to some extent the cells of the latter. The degree of infiltration varies in different glands. In some the "large lymphocytes" are found chiefly in the sinuses and in the medullary cords. Germinal centers are rare. Eosinophile cells are found in large numbers in association with the "large lymphocytes." They are chiefly mononuclear, and resemble the eosinophile cells found in the bone-marrow and the periosteal infiltration. They are also present in large numbers in the connective-tissue trabeculæ, particularly near the hilum of the glands. The number of cosinophiles varies, however, in different glands. In the case of the glands taken from the thymus region the cellular infiltration is very marked. In the greenish gland from this region the lymphoid cells are to a large extent replaced by large lymphocytes, the trabeculæ are farther apart than normally, and the sinuses are wholly or partly obliterated. No germ centers were found in it. In the lymph sinuses of the majority of the glands there is a distinct proliferation of both the endothelium and the reticulum, the reticular spaces being filled with large endothelial cells, "large lymphocytes," and cosinophiles. Numerous degenerating cells are seen. The same appearances suggesting both amitotic and mitotic division are found here as in the periosteal infiltrations and the bone-marrow. In the majority of sections there is no evidence of an infiltration of the capsule or of the tissues about the gland. In some instances, however, there is an infiltration of cells of the "large lymphocyte" type extending through the capsule and into the surrounding

adipose tissue. Such infiltrations are not, as a rule, marked, but bear in general the same character as those found elsewhere.

Hemolymph Nodes.—In the hemolymph nodes from the retroperitoneal region there is a similar diffuse cellular hyperplasia or infiltration of cells of the same type. Germinal centers are absent; the lymphoid tissue is replaced to a greater extent by myeloid tissue of the same nature as that found in the spleen. Numerous mononuclear eosinophiles are present, and great numbers of these occur also in the sinuses and in the connective tissue of the trabeculæ and capsule. The blood sinuses are nearly obliterated and contain but few red cells; there is a reticular and endothelial proliferation, in the meshes of which lie "large lymphocytes," mononuclear eosinophiles, endothelial cells, etc. Phagocytes containing red cells and pigment are fairly numerous in some nodes, but on the whole are greatly diminished. Neutrophile myelocytes are occasionally found, and a few giant cells with large, deeply stained, knobbed nuclei resembling those of the bone-marrow were also seen. In some nodes the greater part of the lymphoid tissue is replaced by a cellular tissue, resembling in all respects that of the sternal and vertebral marrow and the periosteal infiltrations. Such new-formations are analogous to metastases, the surrounding tissues being somewhat compressed and infiltrated. The general picture is that of a gradual replacement of the tissues of the lymph node by the new atypical "lymphocyte" tissue. As a rule such proliferations appear to begin in the sinuses and not in the lymphoid follicles or germinal centers, the latter being latest involved. In those nodes showing such proliferations the atypical cells of the peripheral sinus infiltrate the capsule and pass beyond it into the surrounding adipose tissue. Such extensions beyond the capsule are not in any case marked. Large numbers of eosinophiles occur in the infiltration of the capsule and the adipose tissue. A large proportion of the cells replacing the lymphoid tissue consists also of eosinophile cells. In some nodes the number of eosinophiles is very great. Numerous degenerating lymphocytes are also present. In all of the hemolymph nodes the large lymphocyte cells are most numerous in the blood sinuses. The picture presented is that of a proliferation of these cells beginning in the sinuses and not in the lymphoid tissue.

Lungs.—The sections of the lungs present small areas of emphysema and atelectasis, but the alveoli in general are in a state of moderate distention. Anthracosis is slight or moderate. The larger vessels are distended and filled with white cells, the great majority of which are mononuclear and of the large lymphocyte type. They are of the same variety as those seen in the periosteal infiltrations, bone-marrow, spleen, etc. Eosinophiles are not so numerous as elsewhere; in some vessels but very few are found. As a rule the arteries are more distended with cells than are the veins. The capillaries of the alveolar walls are likewise distended and filled with cells, the majority of which are large mononuclears or large lymphocytes. The general appearance of the sections is that of a leucemic lung. Scattered everywhere throughout the lung are small groups of islands of closely crowded cells, the majority being mononuclears of the "large lymphocyte" type. While many of these islands are in the immediate neighborhood of the large vessels, and undoubtedly in some cases occupy the site of the peribronchial lymph nodes, the majority show no such relations.

There are all possible transition stages between very small collections of cells lying upon the alveolar walls to larger masses filling several alveoli. In these larger masses the alveolar walls directly involved are ruptured or destroyed, the collection of cells filling up and distending several alveoli. Mononuclear eosinophiles are numerous in these masses, but occur to a less extent than in the other regions described above. The majority of the masses consist apparently of free cells; no reticulum can be made out. In some cases the outlines of the alveolar walls included in these cell masses are wholly lost, and there is apparently some fibroblastic proliferation extending into the group of cells, giving it something of a reticulum. The alveolar spaces about many of these small masses contain blood, sometimes also fibrin, and desquamated epithelium. In other parts there are collections of cells containing more polymorphonuclear forms and surrounded by areas of edema and hemorrhage. In these areas the smaller bronchi are filled with cells, the majority being polymorphonuclear. It is evident that such areas are to be interpreted as foci of bronchopneumonia. In the pleura there are present very small groups of mononuclear cells, filling distended capillaries and infiltrating somewhat the neighboring tissues. In general the picture presented by the lung is that of a leucemic condition with infiltrations of cells which are proliferating after the manner of tumor cells.

Heart.—This was preserved as a museum specimen by distending and hardening whole. No microscopic examination has yet been made.

Liver.—Many sections present the appearance of a leucemic liver, the intralobular capillaries being filled with cells, and the islands of Glisson's capsule in many places showing a cellular infiltration. These changes, however, vary greatly in degree in different parts of the organ. As a rule the liver lobules are somewhat smaller than normal, and the islands of Glisson's capsule relatively increased. There is no actual increase of connective tissue except in certain areas where the infiltrated capsule shows also a fibroblastic hyperplasia. The liver cords are atrophic in some areas, and the intralobular capillaries distended, and in many places crowded with cells of the "large lymphocyte" type. The central veins are dilated and in some instances also contain masses

of similar cells. In the cells of the central zone of the liver lobule there is an abundant, yellowish-brown, granular pigment which does not give the iron reaction (hematoidin). The cells of the peripheral zone contain a moderate amount of brown, finely granular pigment which does give the iron reaction (hemosiderin). In some lobules fat drops are also present in the cells of the peripheral zone. The liver cells on the whole show a slight degree of fatty degeneration. While some islands of Glisson's capsule show a marked cellular infiltration, others show little or none. The cells of the infiltration are of the type of the "large lymphocyte," and in the majority of cases have eosinophile granules. In some islands nearly every cell is an eosinophile. In the more densely infiltrated islands evidences of enlargement or growth are shown by the compression and condensation of the liver cells immediately about the island. The impression is gained of an infiltration in which the cells are proliferating.

Smaller masses of cells consisting in many cases chiefly of eosinophiles are also found scattered throughout the liver lobules. These apparently consist of collections of the atypical lymphocyte cells in the dilated capillary, with their further proliferation, and the resulting compression of the neighboring liver cells. Evidences of such pressure condensation and atrophy are clearly seen. In the larger of these masses some reticular proliferation is also seen. In some portions of the sections the collection of cells in the capillaries is so great that the latter appears as cords of deeply staining cells, while the columns of liver cells are in a condition of marked fatty degeneration or simple necrosis, staining a very pale pink or a deep red, the liver-cell nuclei being wholly lost. In these areas there are great numbers of degenerating lymphocytes in the capillaries. Relatively few eosinophiles are seen in the distended capillaries. In many capillaries there is present also a well-marked endothelial proliferation. It is to be noted also that the number of eosinophiles in the large vessels of the liver is relatively much less than in the infiltration in Glisson's capsule, or in the larger collection of cells in the lobules. In interpretation of the liver changes the condition may be regarded as due to the presence in the blood vessels of the liver of cells having the power to proliferate both in the vessels and after passing out into the connective tissue. The process is therefore analogous to tumor metastasis and infiltration.

Pancreas.—Sections show slight atrophy of the lobules, fatty infiltration of the interlobular connective tissue, and beginning post-mortem change. Many cells of the "large lymphocyte" type are present in the capillaries and small arterioles. No infiltration of the connective tissue was seen.

Stomach.—There is a moderate chronic atrophic gastritis with excess of mucous formation in the glands. The interstitial tissue is somewhat increased, and presents numerous small collections of cells which are chiefly mononuclear, many being eosinophile. These small collections of cells bear no especial relations to the lymphoid follicles. The latter are somewhat hyperplastic and contain an increased number of cells of the "large lymphocyte" type. Numerous eosinophiles are present in the follicles and also in the small groups of cells. The small tumor from the fundus consists of bundles of unstriped muscle and fibrous connective tissue running in irregular whorls (leiomyofibroma).

Intestine.—Catarrhal enteritis. The blood vessels of the intestinal wall are collapsed and empty for the greater part. Some contain masses or cords of cells of the "large lymphocyte" type. In the mucosa and submucosa there are very small collections of mononuclear cells, many of which are eosinophile. In one instance a larger mass of similar cells was found in the muscularis, small cords of cells extending from the main mass and infiltrating the surrounding muscle. The peritoneal surface is in many places covered with a layer of free cells, mostly of the "large lymphocyte" type, and containing many eosinophiles. The appearance is not that of an inflammatory exudate. The cells are clumped together in irregular groups, and probably represent free cells of the peritoneal cavity.

Kidneys.—There is slight atrophy, the glomeruli in the majority of fields being more numerous than under normal conditions. The cells of the convoluted tubules show a slight degree of cloudy swelling. The blood vessels of the medullary pyramids are dilated; many are filled with red blood cells with relatively few leucocytes; others are completely filled with cords or masses of cells of the "large lymphocyte" type. In these masses numerous eosinophiles are present. In the blood vessels of the cortex there is a similar distribution of cells. Throughout the cortex there are numerous collections of cells replacing the kidney structure, the largest being two to five milimeters in diameter. They are chiefly situated just beneath the capsule, which is thickened and infiltrated with cells of the same kind. From the main mass of cells irregular cords infiltrate the surrounding kidney tissue following the intertubular connective tissue. In the central portions of these masses all trace of kidney structure may be lost; occasionally an atrophic glomerulus or remains of tubules may be present. There is a distinct new formation of reticulum, and in some cases there is a picture of an interstitial nephritis immediately about the cell mass. About many of the latter, however, the kidney shows no recognizable changes. In others the tubules and glomeruli of the surrounding infiltrated zone are atrophic or compressed or even necrotic. The cells of these masses are almost wholly mononuclears of the type of large lymphocytes, many being eosinophiles. In some cases nearly all of the cells are mononuclear eosinophiles. The cells of the surrounding infiltration are of the same type.

While numerous individual degenerating cells are found, there is no degeneration *en masse* of any portion of these cellular foci. Smaller cell groups are also found throughout the cortex, usually in the immediate neighborhod of a capillary or arteriole filled with white cells. Some of the smaller groups consist wholly of mononuclear eosinophiles. Even in these smaller collections there is a well-marked proliferation of the kidney reticulum. The general picture presented microscopically is that of metastatic growth of cells of the large lymphocyte type, replacing the kidney tissues by means of a slow infiltrative proliferation.

Bladder.—Chronic cystitis. Thickening of mucosa and submucosa. Increase of leucocytes in many blood vessels, the cells being chiefly mononuclear and of the "large lymphocyte" type. No infiltration found.

Prostate.—Collections of mononuclear cells of "large lymphocyte" type in some of the blood vessels. About these there is a limited infiltration, in many cases containing many eosinophiles.

Testis.—Similar collections of cells are found in some of the blood vessels and similar small infiltrations near them. The lining epithelial cells show an unusual degree of pigmentation.

Spinal Cord.—There is some evidence of atrophy and degeneration. (A more complete study of the changes in the cord has been left for another time.) There is no cellular infiltration of cord or meninges. An increased number of leucocytes, chiefly mononuclear, is found in many of the smaller vessels.

Blood Vessels.—The blood vessels throughout the entire body contain an excess of white cells, the majority being mononuclear cells of the "large lymphocyte" type. The number of cells in the vessels differs greatly in different parts. In many places the distention of the lumen, the packing of the cells, and the infiltration of the vessel wall convey the impression of an intravascular proliferation. The proportion of eosinophiles is much less in the vessels than in the tissues.

Pathological Discussion.—Summing up the most important histological changes as shown by the microscopical study of this case, the primary condition appears to be a tumor-like hyperplasia of the red marrow of the vertebræ and sternum with secondary infiltration of the periosteum and neighboring structures, and the occurrence of metastasis-like infiltrations and nodules in the lungs, liver, kidneys, hemolymph nodes, tibial marrow, etc., associated with a cellular hyperplasia of spleen and lymph glands, and evidences of cell proliferation within the smaller blood vessels in various parts of the body.

That the changes in the marrow of the vertebæ and sternum are primary is shown by the fact that the normal marrow elements are completely replaced by the new cells, the marrow spaces enlarged, and the bony trabeculæ rarefied, and by the direct extension of the cell growth in the marrow spaces outward from the bone beneath and into the periosteum. The prevertebral chloromatous tissue is, therefore, nothing more than the periosteum, prevertebral fat-tissue, and fascia infiltrated secondarily by cells coming from the bone-marrow through the blood and lymph vessels, and by direct extension through openings in the bone. The chloromatous tissue over the sternum is similarly interpreted. The greater extent and larger mass of the green tissue along the vertebræ, together with the greater changes in the vertebral marrow spaces and trabeculæ, would indicate that the vertebral condition antedated the sternal.

The cells of the tumor-like hyperplasia of the marrow correspond in their morphologic and staining characteristics to two classes of cells found normally in the bone-marrow, viz., cells of the type variously known as the *large lymphocytes, undifferentiated lymphocytes, large mononuclears,* etc., and cells of the *myelocyte type,* both eosinophile and neutrophile, the eosinophile forms greatly predominating. In general it may be said that about half of the new cells fall into the class of "large lymphocytes" and about half into that of the eosinophile myelocyte. Between the two all possible transition forms exist, and these may be classed with the type which they most resemble. From the character of the transition forms found the evidence is strong that the cells of the myelocyte type are derived from those of the "large lymphocyte" type. This supports the view of Ehrlich and others as to the origin of the myelocytes in the normal marrow.

The condition of the vertebral and sternal marrow may therefore be interpreted as a hyperplasia of the cells of the "large lymphocyte" type or of their parent-cells, a part of the new "large lymphocytes" resulting from this proliferation becoming transformed into myelocytes according to their ordinary course of development under normal conditions. The atypical character of the new "large lymphocytes" and myelocytes produced by this abnormal proliferation may be taken as evidence of the neoplastic nature of the process. This is shown particularly in the loss of the normal differentiation into normal neutrophile and eosinophile myelocytes. In so far as the vertebral and sternal marrow are concerned we have to deal therefore with *a hyperplasia of the large lymphocytes which replaces the other elements of the marrow and in the extent and manner of its growth assumes the character of a neoplasia.*

The neoplastic character of the marrow hyperplasia is further shown by the changes in the walls of the marrow spaces, the infiltration through the blood and lymph vessels, and the direct extension from the bone into the tissues of the periosteum and other neighboring structures. The cells of the infiltration are precisely identical with those of the marrow spaces; there is, therefore, an infiltration of the periosteum and

prevertebral tissues with cells of the "large lymphocyte" and myelocyte types, this infiltration being distinctly neoplastic in character. The infiltrating cells are proliferating in the tissue spaces, and are destroyed and replacing the tissues infiltrated. Such destruction is not of a very rapid or malignant type; the infiltrated tissues show but slight reaction, there is some connective-tissue increase, the walls of many vessels are thickened, and in some of the smaller vessels there is an endothelial hyperplasia. Nerve trunks and ganglia show a more or less decided atrophy, striped muscle fibers all stages of atrophy, and the fat cells of the infiltrated prevertebral adipose tissue also present various stages of pressure atrophy. About the nodular masses of the infiltration the tissues often show some degree of condensation and pressure atrophy. Aside from the purely mechanical effects, pressure and blocking of vessels, etc., the disturbance of the tissues infiltrated is remarkably slight. The growth of the cells through the tissues appears to be largely the result of a direct proliferation in the blood vessels and lymph vessels, the cells growing through the vessel walls, of proliferating in the tissue spaces after having passed out from the vessels. The slight effects upon the tissues may be explained by the assumption of a relatively slight antagonism between the body tissues and the new cells. In general the new cells of the infiltration may be regarded as free cells proliferating in the tissue spaces. Even in the larger and denser masses of the prevertebral region the reticulum is apparently the original reticulum of the tissue more or less thickened, and there is no new formation of blood vessels. The antagonism between the new-growth and the tissue cells must therefore be much less than in the case of the infiltrating tumors, carcinoma, and sarcoma.

From the microscopic appearances the proliferation of the new cells is chiefly by amitotic division. The numerous indentation and constriction forms of the nuclei, the double nuclei, etc., are taken as supporting this view. Division and growth of the cells within the blood vessels undoubtedly takes place. Throughout the body dilated vessels filled with masses of the new cells were found; in many of these the vessel walls is infiltrated or grown through with cells, and about the vessel there is a more or less well-marked infiltration. Evidences of proliferation within the lumen of the blood vessels are especially well marked in the liver.

The nodules in the lungs, liver, kidneys, hemolymph nodes, and tibial marrow appear to be true metastases arising chiefly through the intravascular proliferation of cells and the secondary invasion of the surrounding tissue. As in the prevertebral infiltration and metastatic nodules have but little antagonistic action upon the tissues at the site of the growth; there is but little reaction and but little new formation of reticulum and apparently no new formation of blood vessels. In the kidney alone is the increase of reticulum at all pronounced; in this organ the secondary nodules are in many cases the seat of an interstitial change suggesting a chronic nephritis. In general the effect of the metastases upon the surrounding tissues is chiefly a simple atrophy. In the liver there is also some fatty degeneration and occasionally a localized necrosis about the cell masses. The cells composing the metastases are identical with those of the sternal and vertebral marrow and the periosteal infiltrations.

The blood vessels throughout the entire body show an increase in the number of white cells, the picture presented being that of a marked leucocytosis or leucemia. The greater part of these white cells in the vessels is found to be identical with the "large lymphocytes" of the primary marrow growth, the prevertebral infiltration, and the metastases. As mentioned above, there are evidences of the intravascular proliferation of these cells. The case therefore presents the picture of *a leucemia of the large lymphocyte type associated with a primary neoplastic hyperplasia of the bone-marrow, chloromatous infiltrations of the periosteum, and metastases in various organs. That the leucemia is secondary to and dependent upon the marrow condition there can be no doubt.*

Assuming that the process is essentially neoplastic in its character, it is evident that the new-growth is not identical with any of the known neoplasms. The terms lymphoma, lymphosarcoma, myeloma, etc., cannot be appropriately applied to it, nor is it satisfactory to class it simply as sarcoma. The individual character of its cells and its manner of growth give it a unique place as a neoplasm, and it must fall into a class of its own—a class to which probably all the leucemias belong—due to an abnormal proliferation of the parent cells of the white cells of the blood. To such tumors the term *myeloblastoma* or *leucoblastoma* might be applied, but a discussion of the propriety of such designations will be reserved for another time.

While accepting the neoplastic character of this case of chloroma, the fact remains that nothing is disclosed as to the etiology of such an abnormal hyperplasia of the bone-marrow elements. Intoxication or infection is not ruled out as the etiologic factor, and we are in exactly the same position here as we are in regard to the question of the etiology of neoplasms in general. Pending the discovery of the ultimate nature and cause of such hyperplastic proliferations, they may, with propriety, be classed temporarily with the neoplasms.

It is quite evident in this case that there is no picture of a general disease of the lymphoid tissues of the body, as in certain cases of lymphosarcoma, etc. The changes in the spleen and lymph glands are purely secondary. The germinal centers in these show no signs of excessive proliferation; on the other hand, they are in-

volved last of all. The metastases do not necessarily occupy the site of the lymphoid tissue of the organs in which they are found; but their location is determined independently by proliferating collections of cells in the blood vessels. This is shown particularly clearly in the lungs, stomach, and intestine, where the lymphoid nodes themselves are but little involved, while numerous small collections of cells are found along the arterioles. *The idea of a general lymphatic affection may be rejected here; the process is myelogenous in origin and has become generalized through the blood vessels. It is a general disease only in the sense that the blood vessels contain cells having the power to proliferate intravascularly and to set up infiltrations and metastases.*

The general myeloid character of the spleen and some of the hemolymph nodes may possibly be due to some effort at compensation for the lost marrow function. As a result of the replacement of the normal red marrow by the atypical lymphocyte and myelocyte tissue the formation of the red blood cells must have been greatly diminished. The extreme anemia shown by the patient is thereby explained. No evidence exists of any marked hemolysis. The pigment of the liver may be explained by the lessened splenic and hemolymphatic functions, although it is probable that the changed conditions of the blood plasma may have caused some direct hemolysis. The large numbers of individual degenerating large lymphocytes found everywhere may have given rise to some intoxication. It is very probable that the extreme anemia, either with or without the cooperation of these more doubtful factors, would explain the majority of the clinical symptoms. The involvement of the spinal nerves and ganglia by the infiltrations is also a very important factor in the explanation of the symptomatology. The eye and ear conditions might be similarly explained, though the anemia itself might account for both. The changes in the blood would explain the petechial hemorrhages and the endothelial proliferation. It may be well, however, to repeat here that the primary process—the atypical proliferation of the marrow cells—may be due to an intoxication having a marked myelotoxic action. Of such an intoxication we have no proof.

As to the nature of the green color of the bone-marrow and periosteal growths the case offers no explanation. No evidences of pigment were found in the cells, and no fatty bodies reacting with Sudan III or with osmic acid. The guaiac test was not employed. Hydrogen peroxide and ammonium hydroxide were not used upon the fresh tissue and had no effect upon the fixed material. The supposition that the color might be due to the large number of eosinophiles present would not be supported by other cases of chloroma in which it is definitely stated that few eosinophiles were present. The best explanation of the color would appear to be that it is a true parenchymatous color.

Charcot-Leyden crystals were not observed in this case.

From the above study and discussion the following diagnosis is obtained:

Pathological Diagnosis.—Chloroma (primary hyperplasia of the "large lymphocytes" of the red marrow); secondary chloromatous infiltrations of the prevertebral and sternal periosteum; metastases in lungs, liver, kidneys, hemolymph glands, bone-marrow, etc.; secondary hyperplasia of spleen and lymph glands of thymus region; leucemia (large lymphocyte type); severe anemia; general atrophy and parenchymatous degeneration; chronic atrophic gastritis; lipomata of shoulders; myofibroma of stomach wall.

Epicrisis.—According to the commonly accepted definition at the present time chloroma is a "tumor belonging to the general class of sarcoma, more precisely to the group of lymphoma, lymphosarcoma, so-called leucemic and pseudoleucemic tumors, etc., characterized by its green color and arising primarily in the periosteum, particularly in that of the cranium." The study of the present case as given above shows that this definition must be changed essentially, and that based upon our case a new conception of the nature of chloroma may be formed. In this case, at least, chloroma is a primary tumor-like hyperplasia of certain elements of the bone-marrow; the periosteal condition is purely secondary, and the character of the neoplasia does not warrant its classification as a lymphoma, lymphosarcoma, or simple sarcoma, but assigns it to a class of its own, a class of neoplastic hyperplasias arising from the atypical proliferation of the parent-cells of the white blood cells, hence belonging to the leucemias. Chloroma could therefore be primary in any part of the body in which white blood cells are formed, either under normal or abnormal conditions. From the reported cases of this condition it would appear, however, that the cells proliferating in chloroma are those that produce the large lymphocytes and their descendants and not those giving rise to the small lymphocytes. In addition, the constant localization of the green growths in association with the bones containing red marrow supports the view that chloroma is essentially myelogenous, and the existence of a primary chloroma of the spleen or lymph nodes remains to be demonstrated.

Of the previous writers upon chloroma Gümbel appears to be the first to regard the affection as a primary bone-marrow disease. The recently reported case of Klein and Steinhaus (see above) is, however, a striking confirmation of the findings in our case and of our deductions. In their case the newly formed cells bear the character of neutrophile myelocytes, and represent a higher differentiation than in our own case in which the cells are about half large

lymphocytes and half mononuclear eosinophiles. It is evident, therefore, that different varieties of chloroma will exist in so far as the blood picture is concerned, just as in the case of the leucemias.

The "free" character of the cells of the chloromatous infiltrations and metastases, and of the blood vessels and tissue spaces would easily explain their disappearance under the influence of certain infections, intoxications, x-rays, etc., such as we know occurs in the case of leucemia. The action of such agents could be explained by the assumption of a destruction of cells exceeding or equaling their production, or by an inhibition of the proliferative activity of the parent-cells, or by direct action upon the etiological factor. The destruction of large numbers of the new cells might in itself give rise to an intoxication. Interesting questions are opened up along this line which must be solved later.

Without burdening this paper further with additional details and arguments we think we are justified in arriving at the following conclusions:

CONCLUSIONS.

1. *Chloroma is a tumor-like hyperplasia of the parent-cells of the leucocytes, primary in the red marrow, the periosteum being involved only secondarily.* The possibility of a primary chloroma in any part of the body in which white cells are formed must be considered.

2. As a result of this leucoblastic hyperplasia atypical leucocytes or leucocytes corresponding to some one of the normal types may appear in the circulating blood in varying number. Chloroma is therefore to be classed with the leucemias.

2. The white cells resulting from the atypical proliferation may in different cases attain different stages of differentiation. In some cases they may be of the large lymphocyte type, in others of the type of neutrophile or eosinophile myelocytes. At different stages of differentiation atypical forms may be produced. Whether a small lymphocyte type exists remains to be more definitely shown.

4. It is evident, therefore, as in the case of other leucemias, that the blood picture in chloroma may be very varied, and if this be used for a basis of classification it is possible to designate different varieties of chloroma.

5. It is also possible that in certain cases, or possibly stages, of chloroma the hyperplasia of the parent-cells may reach such a stage that the new forms do not get into the blood stream in such numbers as to give the picture of a leucemia. An aleucemic chloroma is therefore possible.

6. The essential difference between chloroma and other forms of leucemia is the more marked neoplastic character of the former and the formation of the green infiltrations and metastases. The following classification of chloroma is therefore proposed:

Chloroma (chloromatous leucemia).	1. Aleucemic chloroma (?).	1. Small lymphocyte type (?).
		2. Large " "
	2. Leucemic chloroma	3. Neutrophile "
		4. Eosinophile "
		5. Atypical.
		6. Mixed.

7. Chloroma is probably to be regarded as a more malignant form of leucemia. The white cells resulting from the atypical proliferation have the power of multiplying in the blood streams and in the tissue spaces, thus giving rise to masses of cells having the characteristics of metastatic tumors. It is probable that the proliferative activity is proportionate to the lack of differentiation. In the neutrophile and eosinophile forms we should expect a less marked tendency to proliferation; on the other hand, the large lymphocyte and atypical forms would show a greater proliferative capacity, and hence be more malignant. The aleucemic types theoretically would be the most malignant of all, and present characteristics more closely allying them with the sarcomata.

8. The atypical hyperplasia of certain of the elements of the bone marrow leads to the crowding out and replacement of the erythroblastic elements, and a consequent lessening of red-cell formation. Chloroma is therefore attended by and is the cause of a severe *anemia,* to which the chief symptoms of the disease are probably due. This anemia, while it may resemble pernicious anemia in many ways, is essentially *an anemia of deficient hematopoiesis and not one of excessive hemolysis.*

9. The malignancy of chloroma depends, therefore, chiefly upon the replacement of the red marrow and the consequent diminished red-cell formation. The slight antagonism between the new cells and the body cells would otherwise place it among the relatively benign growths, except in those cases in which important nerve structures are injured by compression by the infiltrations or through rarefaction of the bones. The large numbers of degenerating white cells present throughout the body may possible give rise to an intoxication.

10. The cause of the green color remains unknown. It is probably a parenchymatous color. It is possible that processes morphologically like chloroma may lack the characteristic green color. Such cases should be classed with the non-chloromatous leucemias.

11. While classing chloroma temporarily as a unique form of neoplasm, the question of the ultimate etiology of the process is not settled. At present intoxication or infection can no more be ruled out than in the case of carcinoma or sarcoma. We are in the same position here as in the case of neoplasms in general.

INTRACEREBRAL INJECTIONS OF ANTITETANIC SERUM IN TRAUMATIC TETANUS.[1]

BY S. D. HOPKINS, M.D.,

OF DENVER, COL.;

NEUROLOGIST TO THE DENVER CITY AND COUNTY HOSPITAL, ST. ANTHONY'S HOSPITAL AND MERCY SANITARIUM.

TETANUS is strictly a localized infection. In the wound only a small number of the bacilli are found, and they rarely reach the blood or any of the distant organs.

The toxin has been proven to have a particular affinity for the central nervous system, especially the ganglion cells of the anterior horns of the spinal cord and medulla, with which it unites with such great firmness that it is difficult to separate it. Its presence has been demonstrated in the cerebro-spinal fluid. Roux and Borrel conclude that antitoxin injected subcutaneously remains in the blood, and is therefore unable to reach the toxin which is fixed in the nervous system.

Experiments by Meyer and Ransome also support this conclusion, explaining as they do the variation in time (from four to fourteen days) elapsing between inoculation with the toxin and the appearance of symptoms.

It would seem that tetanus toxin does not[2] reach the spinal cord through the blood stream, but by slowly passing along the axis cylinders of motor cells from their terminations. Apparently the myelin sheath acts as a quite impervious membrane, and the toxin enters at the end of the neuron where it is not provided with this sheath. Sensory nerves do not transport the toxin to the cord. The toxin enters the nerve endings from two sources; the first is at the site of the infection, where the toxin is most concentrated, and this probably explains why tetanic spasm frequently begin in the vicinity of the infected part, or are most marked at this point. The rest of the toxin is taken up by the blood and lympth and distributed, to enter the motor nerve endings in small quantities all over the body, and by passing along the motor fibers to enter the cord diffusely, leading to the generalized spasms. The latent period that elapses after injection of the toxin before symptoms appear is occupied by the passage of the toxin along the motor fibers to the spinal cord; if the toxin is injected directly into the spinal cord symptoms appear at once.

From the pathology it is therefore seen that the intracerebral injection of the antitetanic serum is the correct method of treatment for this disease. The following cases tend to confirm this conclusion:

Case I.—F. M., age twenty-one years, occupation shoemaker. Family and previous history negative.

Present Illness.—On May 8, 1903, while working in a livery stable, he stepped on a rusty iron nail, which entered the left great toe. The following two days no symptoms were noticed, except that the wound was tender to the touch. During the fourth day the patient complained of severe headache, associated with stiffness of the posterior neck muscles, which gradually increased in intensity. About 11 A.M. the next day trismus developed and at the same time he complained of pain in the masseter muscles and cramps in the legs.

In this condition he presented himself at police headquarters, and while there he had his his first tonic spasm. At first the spasms came on about every fifteen minutes, but became more frequent, and at the time of admittance to the County Hospital they occurred every two or three minutes. The convulsions were so severe that the patient's body was in complete opisthalonos, although during these attacks consciousness was unaffected. At the time the operation was performed the temperature was 99° F., pulse 115, respiration 24. Had difficulty in swallowing and was unable to talk on account of the jaw being locked.

Examination, May 12, 1903.—Patient was conscious of his surroundings and his condition. All deep and superficial reflexes were increased. There was marked spasm of the masseter muscles causing lockjaw, the teeth being separated about one-half inch and the lower jaw unmovable even with the greatest pressure.

During the examination he had a convulsion

1 Read before The Rocky Mountain Inter-State Medical Society, September, 1904.

2 American Medical Journal, p. 1622, 1904.

in which all the muscles of the body were affected, including those of respiration. All special senses normal. The pupils equal and responding to light and accommodation. Fundi normal.

On May 12 at 6 P.M. Dr. C. B. Lyman and Dr. J. K. Swindt made a small trephine opening in the right frontal bone and injected 20 c.c. of antitetanic serum into the right frontal lobe of the cerebrum. At 6:30 P.M., while under chloroform, he had a convulsion. At 1 A.M. May 13, he had a slight convulsion, with marked trismus. Chloral hydrate grs. xxx was ordered at this time on account of the severe twitching. At 7 A.M. May 14 slight twitching, rigidity of masseter muscles very much less than in previous attacks. After this convulsion chloral hydrate grs. xxx sodium bromide grs. xl were given every six hours.

The trismus, which was constant before the antitetanic serum was injected into the cerebral tissue, continued after the operation for seventy-two hours, when it ceased, as did the spasms. He remained in the hospital until May 26, 1903, when he was discharged, after making a complete recovery.

I am indebted to Dr. I. B. Perkins for the privilege of reporting the following cases:

Case II.—E. F., a boy, ten years of age, while playing with a toy pistol on July 4 last, exploded a blank cartridge, the wad of which took effect in the palm of the left hand, inflicting a somewhat lacerated wound and burying itself deeply in the tissues. He was taken to the police station, where the wound was dressed and subsequently cared for until it had entirely healed.

On July 23, nineteen days after the injury, Dr. I. B. Perkins saw the patient in consultation with Dr. A. A. Clough, who had just been called into the case. Marked trismus was present. During the tonic spasms which came at short intervals the jaws set tightly together. The posterior muscles of the neck, as well as the muscles of the back, became rigid, and the boy appeared to experience great pain. In the interval between the spasmodic attacks, the muscles of the jaws were not to rigid, but they did not relax sufficiently to allow the jaws to be separated. The muscles of the neck and back relaxed slightly in the interval, but contracted instantly on the approach of the spasms, drawing the head firmly backward.

Tetanus was diagnosed and immediate operation was decided upon. While on the way to the hospital slight jars of the vehicle caused severe spasmodic attacks. While being anesthetized, and after he was unconscious of his surroundings the rigidity of the muscles remained and the jaws could not be separated until he was completely anesthetized. When coming out of the anesthesia the trismus returned and was quite marked before the return of consciousness. Roux's point was selected for injecting the serum into the brain-substance. The patient being right-handed, a flap one inch in diameter was made over the right frontal bone, with the open portion of the shoe directed toward the temple. The periosteum was lifted with the flap, and a trephine button one-fourth inch in diameter was removed. The needle of the syringe was introduced into the brain substance to a depth of two inches, with the point directed downward and toward the median line, and 10 c.c. of antitetanic serum was slowly injected during the withdrawal of the needle. Ten more cubic centimeters of the serum were injected in the same manner with the point of the needle directed forward and downward, and not toward the median line. The tissue flap was then sutured in position. The button of the bone was not replaced.

An incision was made in the hand at the point of injury and several small pieces of the wadding were removed.

Reaction following the operation was prompt, and although the trismus returned on the return of consciousness the spasms were not nearly so severe and subsided altogether after forty-eight hours.

Immediately following operation, sodium bromide grs. x and chloral hydrate grs. v were given by enema. This was repeated at varying intervals for several days, and then small doses of the bromide and chloral were given by mouth, sufficient being used to keep the patient sleeping most of the time. The temperature was 99° F. at the time of the operation, and did not go above 99° F. at any time. The highest rate of pulse was 108.

There was some stiffness of the limbs on first attempting to walk, which was two weeks after operation. This was not more marked on one side than on the other, and disappeared in a few days. At this time the patient appeared to be in a perfectly normal condition, having made a complete recovery.

Case III.—A. C., aged twelve years, schoolboy. Always enjoyed good health. On July 4, 1903, while playing with a revolver, it exploded, the contents of the blank cartridge entering the right knee. He was cared for by his mother for fourteen days after the accident, but the symptoms became so alarming that Dr. J. M. Perkins was called to see him.

On examination it was found that he had had headache, cramps and stiffness of the muscles for the past two days. During the examination the patient had a general convulsion on an average of every fifteen minutes. While transporting him from his residence to the hospital the spasms occurred so frequently that it became necessary to use chloroform. On arriving at the hospital the pulse was 150, temperature 101° F., respiration 50. Twenty cubic centimeters of antitetanic serum were injected into the right frontal convolution.

Patient died two hours after operation.

In the three cases reported a trephine opening was made in the right frontal bone half way between the outer angle of the orbit and a point on the vertex, at the juncture of the line crossing over between the two auditory canals. The trephine opening should be small; a small slit made

in the membranes and the needle introduced two inches into the cerebral substance of the frontal lobe of the brain. In these cases the right frontal lobe was selected for the injection because the patients were right-handed, for if any paralysis followed the injection of the serum the center of speech would not be involved. The needle is directed forward and slightly downward.

The mortality of cases of traumatic tetanus treated by the ordinary medical means is very high, averaging about 90 per cent. In 147 cases treated by the intracerebral injection of antitetanic serum the mortality is 61 per cent.

The total quantity of antitoxin injected into the brain varies from five to 70 c.c. at any one time. In the three cases reported 20 c.c. were injected into the cerebral substance at once, and it is the belief of the writer that the success of this method of treatment depends upon the use of large quantities of the serum.

The danger in using serum intracerebrally is due to the fact that it acts as an irritant, and may cause a meningitis, cerebritis or a cerebral abscess. In a number of cases hemorrhages have occurred.

MEDICAL PROGRESS.

SURGERY.

The Bridging of Nerve Defects.—This is a broad subject, embracing as it does nerve repair and degeneration, primary and secondary neurorohaphy, stretching, bringing and so on, but it is nevertheless of the keenest interest to all, since injuries to the nerves are by no means uncommon. Charles A. Powers (*Annals of Surgery*, November, 1904) records the history of his own case of nerve transplantation and records in detail the bibliography so far as it is accessible. His own operation consisted in the implantation of four inches of the great sciatic nerve of a dog in the external popliteal of a man. The operation was done in 1896, and it has, therefore, been eight years since its completion. The case was that of an eighteen-year-old boy, who had been severely injured by a railway train. The popliteal nerve was destroyed in about four inches of its course, and the extremities were, therefore, so far separated as to be impossible of union. The wound area was very dirty, so transplantation was not done until this had cleaned up. The great sciatic nerve of a 35-pound-dog was introduced. A very short time after the operation, sensation, both of temperature, pressure and pain returned. Within six weeks all forms of sensation were normal, but after the lapse of a year there was considerable atrophy of the muscles of the leg in the upper third. Abduction of the foot was, however, impossible. The results were good as regards sensation, but negative as to emotion. Seven years later, like conditions existed. The operation, therefore, may be looked upon as a complete failure as regards motion. In conclusion the author says that more case are needed before any definite conclusion can he reached as to the best means of treating the evils resulting from a gap in the continuity of a nerve. Neuroplasty and implantation should probably be preferred. Bone resection may be advisable in selected cases. Transplantation of foreign grafts should be abandoned, for it may be considered as definitely shown that a piece of nerve has no intrinsic superiority as a graft to any other kind of organized tissue.

Uncomplicated Gunshot Wounds of the Stomach.—Considerable traumatism in gunshot wounds is, according to V. Oppe (*Roussky Vrach*, No. 35, 1904) always an indication for surgical interference, no matter how unfavorable the prognosis. The importance of the lesion lies not in the wound of the stomach but in the traumatism of the large blood vessels. The expectant treatment in uncomplicated wounds of the stomach alone is always followed in a certain number of cases by general peritonitis. Early abdominal section is considered by such surgeons as Mikulicz, Kukula and others, as the only method of treatment of gunshot wounds of the stomach in time of peace. If the wound is located in the abdominal walls corresponding to the site of the stomach, then it remains to decide as to whether it extends into the peritoneum and whether the stomach is invaded. At times it is not difficult to decide this question, but frequently it can not be easily determined. The author cites, among others, the case of a girl of eighteen years, who shot herself in an attempt of suicide. The wound was located along the left mammary line, below the nipple. Four hours later abdominal section was performed as the author suspected invasion of the stomach. Its anterior surface proved to be the site of a wound 1½ cm. long, there was no prolapse of the mucous membrane, nor was there any exudation of the gastric contents through the wound. The posterior wall of the stomach contained no wound of exit, and no bullet was felt in the cavity of the stomach. The peritoneal cavity was filled with 800 c.c. of a warm saline solution. The postoperative course was uneventful. The sutures were taken off on the sixth day. Examination of the abdomen with X-rays failed to discover the whereabouts of the bullet, which, however, was found located in fecal masses in the rectum, and extracted without difficulty. When the symptoms point to an undoubted trauma of the stomach, operative interference becomes imperative so as to prevent a possible purulent peritonitis. However, Réclus is a warm defender of expectant treatment, as according to him the healing of the wound is frequently brought about by the falling into it of the mucous membrane which thus serves the purpose of a tampon. But Klemm has shown experimentally that such healing is of infrequent occurrence, as the peristaltic movements of the organ must necessarily prevent the closing of the wound. Abdominal section is indicated, in gunshot wounds of the stomach alone, only in recent cases. But if the patient comes under the surgeon's care on the third day and later, then the question as to the operation will depend on the peculiarities of the given case, for the absence of symptoms pointing to an invasion of the peritoneum during the first twenty-four hours will serve as an indication that the wound of the stomach does not permit the exudation of its contents into the peritoneal cavity.

Cancer of the Larynx.—The question of treating this dreadful lesion still remains open, but American and English operators are thoroughly awake to the importance of reaching some definite and satisfactory method both of recognition and of treatment. Felix Semon (*Lancet*, November 5, 1904), concludes first, that here as elsewhere early diagnosis is paramount. For this purpose it is absolutely essential that all idea that a patient suffering from malignant disease of the larynx shows grave constitutional symptoms early must at once be eradicated. For this time-honored belief must be sub-

stituted among laymen and practitioners alike the belief that persistent hoarseness occurring in middle-aged or elderly people is sufficient evidence, other things being equal, to justify radical operation. These are the cases which yield the most brilliant results. Although clinical manifestations and physical examination will almost invariably serve to give a correct interpretation at the hands of experienced examiners, no case should be operated upon radically without a confirmatory laboratory report of a portion of tissue removed for microscopical examination. This, however, should be done only if the patient previously consents to immediate radical operation in the event of the microscope confirming the clinical diagnosis. Nevertheless, as in other cases of malignant disease, the microscope is by no means an infallible guide in these cases. Should its evidence be negative or inconclusive, the intralaryngeal removal and microscopical examination of fragments should either be repeated, if necessary, several times, or if the clinical symptoms do not warrant postponement exploratory thyrotomy should be undertaken. The intralaryngeal method is from its very nature unsuitable for the radical removal of malignant new growths of the larynx. Subhyoid pharyngotomy, apart from being applicable in a very small number of cases only of malignant disease of the larynx, is still *sub judice* with regard to its advisability in such cases. Thyrotomy, if undertaken in suitable cases, and at sufficiently early period, and if performed on the modern lines which experience has shown to be successful, is a perfectly ideal operation in intrinsic cancer of the larynx. Hemilaryngectomy comes into question only when it is found after opening the larynx that mere thyrotomy will not suffice. When performed, it may be accompanied by removal of the tributary lymphatics, even if apparently not diseased. Total laryngectomy should be exclusively reserved for extrinsic, and for those cases of intrinsic cancer, in which both sides of the organ are affected, and in which the disease has proceeded too far to be eradicated by milder measures. When performed it should be accompanied by the removal of the laryngeal lymphatics on both sides of the neck.

MEDICINE.

Clinical Study of Actinomycosis.—The increase in frequency of this disease, following directly upon the concentration of inhabitants in our overcrowded cities, makes a recognition of the condition of particular importance. If infection should happen to be superficial, of course surgical measures are at once indicated. Free excision is the most rational method of treatment, unless, as is often the case, the growth is so situated as to render this impossible. In this event the medical treatment should be instituted and iodide of potassium appears to be a specific in early cases at least. Robert Knox (*Lancet*, October 29, 1904), states that the remedy must be pushed rapidly to its extreme dosage limit. Apparently in this case, as in the case of others of the granulomata, the patients are singularly tolerant of the drug, it being almost impossible to induce iodism. In the case of two patients whose cases were reported by the author, one in five months took 16,320, or an average of 103 grains daily, without exhibiting any undue symptoms. Indeed the patient appeared to improve much while taking the iodide and missed the drug when it was omitted. The other patient took 40 grains daily and improved under the treatment. The most important point in this condition, as in tuberculosis, is to make an early diagnosis. Unfortunately, this has not, up to now, been accomplished until the very latest stages, when, unless the case be susceptible to surgical treatment, the patients are beyond hope. A similarity which exists between actinomycosis and tuberculosis is unfortunate from a therapeutical point of view, because the one disease is so frequently mistaken for the other. The author points to the interesting fact that three members of a single family were the subjects of infection, this being another point in common with tuberculosis.

Bitemporal Hemiplegia.—Blindness on the temporal sides of the eyes, so that objects can be seen only with the nasal portion of each eye, is reported by Flavell B. Tiffany (*Medical Fortnightly*, October 10, 1904), showing the anatomy, lesion and treatment of a case. The fibers from the temporal halves of the eyes do not cross, but come up to the chiasm and diverge to the base of the brain on the same side, while the fibers from the nasal halves of each eye cross and go to the base of the brain on the opposite side. Should a lesion be located at the chiasm involving the decussating fibers only, the part of the eye from which those fibers come would be affected, but the fibers from the temporal sides, as they do not cross, would remain uninvolved. In the case reported the eyes troubled him for five years, and on examination it was found that if the left eye were closed objects on the left or nasal side could be seen, all objects on the right or temporal side were invisible. Also, if the right eye were closed objects on the right were visible, those on the left being entirely out of view. No history of injury, syphilis or poison was obtainable, the patient had had rheumatism off and on, and an attack of grippe three years before. It is thought the lesion was due to the toxins, and an exudate due to grippe. The treatment consisted of one-half grain of pilocarpine, night and morning, inunctions of blue ointment and electro-vibrator massage for several weeks, followed by a tonic of quinine, iron and strychnine. Massage being kept up two or three times a week for about six weeks.

Unusual Forms of Infectious Disease of Central Nervous System.—Successive degeneration of the spinal structure, neither inflammatory nor anemic in origin, observed by James J. Putnam and George A. Waterman (*New York Medical Journal*, October 29, 1904), shows the effect of some toxins on the cord. Progressive impairment of sensation and motion and spinal reflexes which commenced in the lowest sacral segment rapidly advanced, through the lumbar, dorsal and cervical regions, to involve the medulla and ended in unconsciousness and death in about ten weeks' time. The progress of the disease was associated with irregular fever and pulse, leucocytosis and the various symptoms of myelitis. Post-mortem examination shows extensive destruction and degeneration of the cord, with formation of fat granules. The anterior roots are more degenerated than the posterior, but in no place is there evidence of inflammatory condition or impairment of nutrition. The blood serum culture proved sterile and no lesion was found in the brain. There are various forms of nervous disease caused by toxic influence, but it is unusual to see the different segments of the cord successively attacked.

Gastric Ulcer in Children.—One of the diseases from which the young are almost immune is gastric ulcer, especially in the chronic form. In fact, certain clinical authorities actually deny the occurrence of such an affection; nevertheless, E. G. Cutler (*Boston Med*

and Surg. Jour., October 6, 1904), has been able to collect 26 well authenticated cases out of the literature, of which 24 had an autopsy report. The distribution of the ulcers was very variable, showing no marked predilection for any particular area. The etiology of the lesion is rather obscure. In some of the cases developing immediately after birth, of which there were six, the blackened, lacerated appearance suggested effusion of blood into the mucous membrane as the cause of the necrosis. In this connection it is noted that numerous instances of hematemesis or melena shortly after delivery are reported, in which the erosion was probably not so extensive as to prevent rapid healing. In six of the acute cases the ulcer was an intercurrent affection, occurring after several hours, or one of the infectious diseases. A remarkable fact is the preponderance of females, 18 in 29 cases, as in adults. The symptoms in infants are simply melena, hematemesis, restlessness and prostration. In older children, pain and tenderness, usually in the epigastrium, were premonitory symptoms. Vomiting occurred in 16 cases, and was always acid. Hematemesis occurred in 11 cases. The treatment consists in bed rest for three weeks, hot fomentations to epigastrium and a milk diet.

Are There Other Carriers of Malaria than Mosquitoes?—J. POWELL (*Med. Rec.*, November 19, 1904) agress with several other recent writers who believe that mosquitoes do not form the only medium of transmission of malaria. From May 28 to Sept. 1, 1904, ten cases of tertian intermittent fever were observed among the enlisted men in the command at Fort Hamilton, N. Y. All but three of these cases occurred in the same company organization which last year also furnished more than its quota of cases. The barracks for this company are located on the highest elevation in the Post, overlooking the Dyker Meadows, a more or less salt marsh, and are situated but a short distance from the Post dumping grounds. They are also near the battery stables. With the exception of a single *Anopheles* killed in the writer's own quarters, careful examination of the stagnant water in this vicinity, as well as search throughout the entire Post failed to reveal any mosquitoes that differed from the *Culex solicitans* or *Culex pungens*. The author therefore concludes that there is some other unknown factor concerned in the transmission of malaria.

The Value of the X-ray for the Medicolegal Expert.—The various ways in which the X-rays may be applied for this purpose are described by IMMELMANN (*Berl. klin. Woch.*, October 24, 1904). In addition to the application in accidental injuries, it is of signal value for determining the age of premature fetuses. The epiphyses of the long bones are known to remain permeable to the rays until after birth, with the exception of that of the distal end of the femur, which is visible at the thirtieth week of fetal life. As this is the time legally set for a possibility of the child having been viable, it is the duty of the one making the autopsy to fully demonstrate this point. It may also be necessary to determine whether the child has breathed or not, and this may be readily done by the X-rays. The author has shown that unexpanded lungs give a dark shadow like that of muscle, while lungs which have been filled with air readily permit the rays to pass through, and hence give no shadow. A number of other fields, including the important one of military surgery, have also been favorably exploited by this agent.

Treatment of Basedow's Disease.—An interesting case of this disease, in which the milk treatment advocated by Lanz was employed with excellent results, is reported by O. E. LADEMANN (*Am. Med.*, November 19, 1904). This consists of feeding patients afflicted with exophthalmic goiter with milk from thyroidectomized goats, and is based on the theory that in thyroid cachexia a poison is circulated in the economy, which under normal conditions by the thyroid secretion, and the secretions of such a cachexia, if used in Basedow's disease, might have an antagonizing effect on the poison of this affection. He treated a number of patients with milk from thyroidectomized goats with excellent results, the symptoms improved and the weight increased. The writer's case was a severe one, the exophthalmos and the goiter being very prominent, there was considerable emaciation, choreiform movements and a leucopenia. The milk was given in varying quantity, from 2 to 3 pints daily. Improvement was slow, but constant, and in three months she had gained about 13 pounds. The author believes that instead of the milk having a direct antagonistic action, the process is one of neutralization, or possibly combination, and the effects last only as long as the milk is given. Moreover, the severer the exophthalmic goiter, the more milk is required to neutralize. He does not consider that this treatment is a specific for Basedow's disease, but believes that further observations are necessary to establish its value. He would also suggest the use of desiccated thyroidectomized milk in the form of tablets, as preferable to that in its natural state, and with these he is at present experimenting.

Postdischarge Mortality Among the Patients of the Adirondack Cottage Sanitarium.—The permanent or ultimate results of sanitarium treatment of pulmonary tuberculosis are discussed by L. BROWN and E. G. POPE (*Am. Med.*, November 19, 1904), who base their conclusions on statistics of 1,542 patients treated in this institution. The real test of this treatment is not the immediate, but the ultimate results. The lack of uniformity in classification renders the comparison or the combination of the results of various sanitaria extremely difficult. The classification on the "ability to work" is beset by so many difficulties in America, that it is rendered of little value. The mortality among patients discharged in various conditions affords the best method of studying the permanent results of sanitarium treatment. Of those discharged apparently cured, 93 per cent. of the expected living are alive; of the disease arrested, 65 per cent.; of the cases discharged with active symptoms, 23 per cent. The death-rate among the apparently cured patients is during the first ten years about three times the ordinary death-rate. The death-rate among the patients discharged with the disease arrested increases during the first few years to many (10 to 15) times the normal death-rate, but afterward decreases. Nearly half the patients discharged with an active disease, died in the first two years. Patients between 30 and 40, when discharged apparently cured, seem to relapse less than younger patients. This tendency is little, if at all marked among the patients discharged with the disease arrested. Incipient cases seem to relapse less than advanced, when both are dischaged in the same condition.

The Effect of Cold on the Arteries.—It is almost universally believed that the first effect of cold is to contract the arteries and that of moderate warmth, to relax them, but this has never been di-

rectly proven. Another point which has not been solved is, what is the condition of the vessels on either side of the part to which the stimulus is applied? An investigation of this character has been instituted by M. Herz (*Berl. klin. Woch.*, November 7, 1904) with Gärtner's method of recording the pulse. The lever of the instrument was adjusted to the middle of the forearm, and then cold applied either above or below this point in the form of an ether spray. The results failed to support one of the most accepted tenets of hydrotherapy, as it was found that the large artery which carries the blood from the place where the irritant was applied, to the point under observation the sphygmograph, failed to contract under the influence of cold. The pressure in the small arteries distal to the point where the cold is applied, rises, because these vessels retract in the tissues supplied by them. On the other hand, the tension decreases in the small arterial twigs, central to the same point, because these vessels dilate. When warmth was used instead of cold, the results were so inconstant that no conclusion could be formulated. The results of these investigations are summarized as follows: The application of cold does not influence the diameter of a large arterial branch. The tension in the minute branches peripherally situated, is increased by the contraction of the capillaries, while in the centrally disposed set of vessels the tension is diminished, because of the dilatation of the corresponding set of capillaries.

Serum Therapy of Snake Bite.—With our increasing territorial acquisitions in and about the equator, all these problems of tropical medicine become more and more important. George Lamb (*Lancet*, November 5, 1904) says that it has been shown for a considerable period that animals treated with the venom of poisonous snakes, such as the cobra, for example, yield varying quantities of serum, which is antitoxic toward that poison. Calmette was the first to produce an antivenomous serum in sufficient quantities for therapeutic purposes. This was prepared with a mixture of snake venoms, in which mixture, however, cobra poison greatly predominated. He claims that this serum was active against the venom of all species of snakes, a claim based on the conception that all snake venoms are alike in physiological action, and only differ from one another in their degree of toxicity. Not long after this, it was shown by the author in India and by Martin, in Australia, that this claim was fallacious. From a long series of observations and of experiments, the author comes to the following conclusions: (1) Antivenomous sera are markedly if not absolutely specific, even between the venoms of species of the same genus, hence in any case of snake bite the serum prepared with the venom of that series which has inflicted the bite must always be used. (2) The difficulties in collecting the poisons of different species of snakes in sufficient quantity for purposes of immunization are apparently very great. (3) Up to the present the only sera which have been used practically are the one prepared by Calmette and the one prepared at this institute with pure cobra venom. Both these sera are practically specific for cobra venom. (4) As the neutralizing power of these two sera is not great and as a cobra can inject a large amount of venom, the serum must be given in large quantities; as much as from 300 to 400 centimeters, even when given intravenously would be necessary in some cases. If given subcutaneously, from ten to twenty times this amount would be required. It should, therefore, always be given intravenously. (5) Experiments on dogs and the records of cases of cobra bites in man bear out these calculations. (6) It is evident from the above considerations that it is a question as to whether the advantages to be gained by the serum treatment of cases of snake bite are at all commensurate with the cost entailed in the preparation of the sera.

Cause of Glycosuria After Morphine.—A dose of morphine will frequently cause the appearance of sugar in urine; and if morphine be given to dogs the urine will frequently reduce copper and bismuth, turn the plane of polarized light and ferment. The amount of glucose is small, and rarely exceeds 5 to 6 pro mille, or about two grams per day. R. Luzzatto (*Arch. f. exp. Path. u. Pharmak.*, Vol. 52, Nos. 1 and 2) has discovered that this glycosuria is not caused by an increased permeability of the kidneys, as in the case of phloridzin, since the blood-serum contains considerably more glucose after morphine than normally. The influence of food is very slight, for glucose will be excreted if meat alone or meat plus sugar be given, and even during the fasting stage, if this is not prolonged beyond five or six days. After long-continued administration, a tolerance is established, the animal will no longer exhibit symptoms of poisoning, and glycosuria will not appear. Morphine, as well as chloroform, may act upon the medulla oblongata or the general nervous system, like the piqure of Bernard. Owing to this irritation, the liver will be freed of its glycogen, and this will then give rise to hyperglycemia and glycosuria. Or the glycosuria may depend upon an increased breaking down of proteids, or, lastly, the sugar may pass into the urine, owing to deficiency of oxygen. Morphine will increase the excretion of nitrogen, phosphoric and uric acids, but since the glycosuria stands in absolutely no relation to the degree of proteid decomposition, it is unlikely that the latter can be held responsible.

Phosphaturia.—Phosphaturia is a physiological phenomenon if it occurs after a large meal, after repeated vomiting or gastric lavage. In the following conditions, a pathological excretion of phosphates may occur: (1) In chronic inflammatory affections of the genito-urinary tract, particularly chronic gonorrhea. (2) In neurasthenia and other nervous diseases. (3) In chronic dyspeptic and rheumatic affections. In several cases observed in children, the following symptoms were noticed: Milky turbidity of the urine, emaciation, anemia, loss of appetite, headache, perspiration. Marked nervous disturbances were itching, paresthesiæs, pains in the joints, increased reflexes. Circulatory symptoms, such as palpitation of the heart, rapid pulse and murmurs were not uncommon and umbilical pain, diarrhea, mucoid stools and vomiting were observed. The discharge of urine was not interfered with, the amount and specific gravity were normal. Microscopically, amorphous and granular phosphates, occasionally triple phosphate, neutral phosphate of lime and oxalate of lime were found. The reaction was alkaline, amphoteric or faintly acid. Four possibilities may be quoted to explain the presence of these salts in the urine: (1) A deficiency of acid; (2) an excess of alkali; (3) an excess of calcium or magnesium; (4) a combination of the above factors. Physiological albuminuria is thus easily explained. After an excessive meal or

after gastric lavage, so much acid is removed from the stomach, that the blood is too alkaline. Vegetables, on the other hand, will increase the alkali in the blood directly, since they are rich in carbonated salts, while patients with genito-urinary disease often take large amounts of alkaline water and milk. Neurasthenics frequently suffer from chronic constipation, and for this reason consume large quantities of vegetables, which would easily account for the phosphaturia. There is, however, a separate class, where the phosphaturia is the primary condition. In children, at least, this is not really a phosphaturia, but a calcariuria, since the amounts of phosphoric acid voided are normal, but the lime increased, sometimes to five times its normal amount. The nervous symptoms are probably due to a retention of lime, since administration of lime will aggravate the condition, without affecting normal individuals. The treatment consists chiefly in the proper regulation of the diet. Potatoes, apples, cereals and meat are permitted, since poor in lime, but milk, eggs, leguminose vegetables, berries and fruits should be avoided. Meat may be allowed two or three times daily, together with butter and cream, much sugar and pastry. In intractable cases, rest in bed may do good. Muriatic and phosphoric acid have been recommended, but have little influence on the condition.

Importance of Iron in Animal Economy.—Iron is an element without which life would be impossible, and it is therefore not suprising that it has been detected in every organ of almost every animal and in a great variety of the higher and lower plants. Thus, A. Baldoni (*Arch. f. exp. Path. u. Pharmak.*, Vol. 52, Nos. 1 and 2) has detected an appreciable percentage in organs free from blood, such as the cornea, lens and vitreous body of the eye. The muscles and liver of animals not possessing hemoglobin, such as the lobster, are quite rich in iron. Finally, Iceland moss was examined to determine if this drug really possesses the therapeutical value in anemia so frequently claimed for it. The average figures obtained were only 0.0198 per cent. of the dried moss, which is about five times less than has been found by other observers.

Tubercle Bacilli in the Urine.—Rosenberger (*Am. Med.*, December 3, 1904) examined the urine tubercle bacilli in twenty-five cases of pulmonary tuberculosis, the residual urine being obtained by means of a sterile catheter. In no case was tuberculosis of the genito-urinary tract diagnosed or suspected, but the sputum always showed tubercle bacilli. Careful examination revealed a few, isolated tubercle bacilli in five cases. No clumps nor groups of bacilli were observed, as usually seen in cases of tuberculous cystitis, nephritis, etc. Intraperitoneal inoculations were made into guinea pigs, 2 c.c. of the sedimented urine being used. As a result of the inoculations three animals died, and in one of these no tubercle bacilli had been found in the urine of the individual. The surviving animals were kept under observation for three months and then killed; in not one of them was there any evidence of a tuberculous process. Rosenberger concludes that although the small number of cases scarcely warrants a positive assertion, still it is safe to say that in pulmonary tuberculosis the tubercle bacillus is found in the urine in only a very small percentage of cases.

Two Cases of Henoch's Purpura.—O. C. Smith (*Med. Rec.*, December 3, 1904) describes two cases of this disease. The first was that of a boy of nine, who developed purpuric spots on the legs and abdomen two days after a blow on the abdomen. In the course of the next week there were severe abdominal pains, the purpura became general, and the albuminous urine contained blood. Two weeks after the onset of the symptoms there was evidence pointing to intestinal obstruction, and a laparotomy was performed. The intestine was found collapsed and presenting many ecchymotic spots. The intestines were lifted up and douched with salt solution, and a quantity of this was left in the abdomen. Relief of the intestinal symptoms followed the operation, but a month later the patient died of the renal condition, which had not been improved by decapsulation of both kidneys. The other case, a boy of sixteen, presented symptoms in general similar to those of the first patient, and was also treated by laparotomy and filling the abdomen with salt solution. Improvement followed, and he was discharged cured four weeks later. From a consideration of the cases described in the literature, numbers of which presented abdominal symptoms, the author believes that Henoch's purpura should not be regarded wholly as a medical disease, and owing to the possibility of pathological changes in the stomach and intestinal walls, giving rise to conditions susceptible of surgical treatment, he considers that in cases presenting grave abdominal symptoms, exploratory laparotomy is not only permissible, but is indicated. An important deduction from the author's two cases is that in each one filling the abdomen with salt solution was followed by a reestablishment of peristalsis in the paretic intestine, and in the cessation of vomiting.

THERAPEUTICS.

Skimmianin, a New Alkaloid.—By a comparatively simple process, J. Honda (*Arch. f. exp. Path. u. Pharmak*, Vol. 52, Nos. 1 and 2) has succeeded in isolating skimmianin from *Skimmia japonica*, a plant indigenous to Japan. Injection into frogs, this alkaloid causes muscular spasm at the site of application, gradually extending to the neighborhood. The reflex irritability is first increased, then diminished, but the actual work done by the poisoned muscles is not increased. The pulse is slowed, even after atropine, probably due to direct action on the heart muscle. In rabbits the chief symptoms are opisthotonus, dyspnea and contraction of the pupils, which disappear rapidly after non-fatal doses. In chloralized animals a fall of pressure may be observed, which is due to direct action on the heart, while the subsequent rise must be ascribed to compensatory contraction of the peripheral vessels. The alkaloid behaves like a feeble base, but is not allied to caffeine, since it does not increase the working power of muscles and possesses no diuretic action.

Roentgen Treatment of Malignant Diseases of the Breast.—C. L. Leonard (*Am. Med.*, December 3, 1904) points out the analogy between the process of healing in atropic scirrhus of the breast, and that resulting from the Roentgen treatment. He believes that the indications for early thorough surgical removal of the malignant tissue and the adjoining lymphatics have not been changed by the advent of the Roentgen method of treatment. Roentgen treatment in malignant disease of the breast can as yet point to only one class of cases in which its use is indicated primarily. In this class surgical intervention is contraindicated by modern

pathology and clinical experiences. In all other cases, surgical removal of the breast with the tumor and the adjacent lymphatic areas is always indicated. Wherever possible an attempt should be made to remove the greater part of the malignant tissue, even though the operation can be only palliative. With the aid of Roentgen treatment even large ulcerating areas can be healed, while the toxemia is lessened and the Roentgen treatment facilitated. The value of the milliampèremeter, as a basis for comparing technic in radiotherapy, cannot be overestimated. Its invention makes a marked advance in treatment possible. The results obtained in favorable cases can be measured by this standard, and similar conditions can be produced in other cases, not only by the operator himself who produced them, but by any one possessing the requisite technic and apparatus. It will simply be necessary to know the dose employed in terms of standard dosage. Of the twenty-six cases of malignant diseases of the breast reported in his paper, the patients having been under treatment since 1900, twelve are dead and two, not heard from, are also probably dead. Nearly half the patients are living to-day. One, however, cannot expect to live more than six months. One has lived two years, and yet disease is certainly present. Nine remain apparently cured. Seven patients, or a large proportion, considering their condition when first seen, have lived over a year after their operations. This is not long enough to determine the permanence of the cure, but the results are encouraging, being better than those of the average operator, and the results obtained in some of these cases, even if the cure is not permanent, are enough to justify the employment of this method and to attest its value.

Nitroglycerin in Erysipelas.—This drug has been used with apparently good results by J. W. WHERRY (*Jour. Am. Med. Ass'n*, November 5, 1904). The cases were all well marked and the writer gave 1-100 gr. every three or four hours. An ointment of zinc oxide and ichthyol was also used, but this served merely to allay the discomfort. All these cases presented several features in common as the result of this internal treatment—a reduction of temperature, moist skin, good appetite, steady pulse after the first day, absence of prostration, and fairly rapid disappearance of the inflammatory process. The writer recommends it for further trial.

New Treatment of Rheumatism.—Injections of sterilized sodium salicylate, directly into the joints in articular rheumatism are highly recommended by A. SANTINI (*Wien. klin. therap. Woch.*, September 4, 1904). For the elbow-joint the needle is introduced obliquely above the olecranon, and for the knee by either side of the patella. In the hip and shoulder-joints it is often difficult to reach the interior of the joint; in such cases a periarticular injection is preferable. The strength of the solution should be three per cent., so as to be isotonic with the blood, and three to four cubic centimeters are usually sufficient. When the synovial cavity is distended with fluid, it may be advisable to withdraw a little serum. The only untoward symptoms noticed were a slight temporary increase of pain. In all cases a cure was accomplished much more rapidly than after internal or endermal use of salicylic acid

Synthetic Adrenalin.—Synthetic adrenalin, or at least synthetic substances acting like adrenalin or suprarenin, have been prepared by ROSER (*Pharm. Ztg.*, XLIX, p. 874), and described by H. Meyer at the International Congress of Physiologists at Brussels. The pharmacological investigation of the synthetic, chemically methylamino-ortho-dioxyacetophenon, showed that qualitatively it exhibited an effect exactly like that of suprarenin, not only so far as the peripheral vasoconstricting action following intravenous injection is concerned, but also as to the action on the smooth muscular fiber, and the causation of diabetes. It was further found that a series of homologous compounds (amino-ketones, ethyl-amino-ketones, etc.) exert a similar action.

PRESCRIPTION HINTS.

Hemorrhoids.—The internal variety are rendered painless for a period of from two to three hours by a suppository of the following:

℞ Orthoformi.	gr. xv	(1.0)
Ext. belladonnæ.	gr. i	(.06)
Ol. theobromæ.	q.s.	

Fiat in suppos. No. X.

Or, if there be a tendency to slight hemorrhage from minute fissures, etc.:

℞ Acidi gallici	gr. xv	(1.0)
Ext. opii	gr. i	(.06)
Orthoformi	gr. xv	(1.0)
Ext. belladonnæ	gr. i	(.06)
Ol. theobromæ.	q.s.	

Fiat suppos. No. X.

Gouty Headache.—This dyscrasiac condition is often difficult to overcome. Those patients with accompanying anemia being particularly refractory. The following prescription has given relief to many:

℞ Sodii phosphatis	gr. xv	(1.0)
Acidi salicylici	ʒ v	(20.0)
Ferri pyrophatis.	gr. lxxv	(2.3)
Aquæ.	q.s. ad ʒ vi	(180.0)

ʒ iv qr. four hours.

Palatable Syrup of Quinine.—*Merck's Report* gives the composition of such a syrup, as follows:

℞ Quinine sulphate	2 dr.
Cinchonine sulphate	2 dr.
Dil. sulphuric acid.	to dissolve
Oil orange.	to flavor
Saccharin.	8 gr.
Alcohol.	2 fl. oz.
Glycerin.	2 fl. oz.
Syrup.	to make 16 fl. oz.

Dissolve the quinine and the cinchonine in 4 fl. oz. of the syrup with the aid of the acid. Dissolve the oil of orange (or other suitable flavoring) and the saccharin in the alcohol and glycerin, and add this to the quinine solution; finally, add enough syrup to make the mixture measure one pint. Such a syrup is of value as a tonic in the malarial cachexiæ and in other adynamic conditions.

Multiple Warts.—Dr. Mantelin (*Merck's Report*) reports the case of a little girl of eleven years, who had had for three years numerous warts on her lips and hands; and these warts were completely cured in one month by the administration of 10 gr. of magnesia daily, and the following local application:

℞ Chloral.	90 gr.
Acetic acid.	90 min.
Salicylic acid.	1 dr.
Ether.	1 fl. dr.
Collodion.	4 fl. dr.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, DECEMBER 10, 1904.

ERYSIPELAS: A MUDDLE.

FOR a number of years prior to 1901 erysipelas appeared in the reports of the New York Department of Health under the classification "Septic diseases," the group including erysipelas, septicemia, pyemia and puerperal fever. In 1901, for some reason not explained, the disease was removed from this classification, and in the last annual reports of the Department, erysipelas takes its place in the list of general epidemic diseases.

There have been no epoch-making bacteriological discoveries concerning erysipelas in the period referred to, and so far as we are aware, the Health Department has not recently introduced any new method having for its end the prevention of epidemics of the disease in question; in fact, erysipelas is a disease to which health officials, whether in New York City or elsewhere, pay but little attention. In this city the disease is nominally notifiable; but it is not one of those which physicians are really expected to report, and no official attempt is made to insure isolation or to control methods of treatment.

Obviously, the number of cases occurring in the course of the year cannot be stated. The death-rate, however, does not tend to increase, and it would appear from a study of the following figures that the easy official attitude toward erysipelas has not proved inimical to the public welfare:

Year.	Number of Deaths Due to Erysipelas.	Estimated Population of Greater New York.
1899	230	3,550,053
1900	316	3,444,675
1901	198	3,536,517
1902	186	3,632,501

The practice of hospitals in this city regarding erysipelas reveals an interesting state of affairs. Bellevue Hospital, with its erysipelas ward of 20 beds, 10 for men and 10 for women, represents the only special provision made by or in the city for the treatment of the disease. The private charitable hospitals do not admit cases of erysipelas, and cases developing in their wards are, in many instances, transferred to Bellevue Hospital for treatment. Some hospitals consider isolation to be indispensable in all cases; others take alarm when the disease develops in surgical wards, but are indifferent when it makes its appearance among medical cases. In the smaller private hospitals, cases of erysipelas are not openly accepted, but are often secretly admitted under other names.

The variation in the practice of institutions reflects the uncertainty of the medical mind on the subject in question. Abbott, in his "Hygiene of Transmissible Diseases," makes no mention of erysipelas; the omission can hardly be accidental. W. Gilman Thompson, in his "Practice of Medicine," describes erysipelas as a distinctly contagious disease, and urges extreme measures of precaution upon those who have been in contact with cases. His recommendation that physicians who have handled erysipelas subjects "should not visit puerperal or surgical cases for several weeks," aptly illustrates the dread of the disease which, if not general, is at least widely shared. These citations are purposely drawn from textbooks in actual use in representative medical schools. In a practice of several years, in one of the large hospitals of New York City, we have not once seen a clear case of the direct transmission of erysipelas from one patient to another, either in the medical or the surgical wards. But older surgeons are thrown into wild alarm at the sight of the dread eruption, recalling the fatal epidemics of their younger days. Content with the precautions commonly taken in large surgical wards, where clean cases and pus cases are treated side by side, surgeons will calmly disre-

gard the presence of streptococcus in the ward until, in a susceptible case, erysipelas appears; at that moment the case becomes one to be shunned, though the wound conditions and the chances of infection are unchanged.

The correct handling of cases of erysipelas is a practical clinical question, which has not been made clear by bacteriological research. At present the disease cannot be said to be epidemic; but it is important enough to merit greater attention on the part of the Health Department, through whom, more readily than by any other means, the practice of hospitals and the profession in regard to the treatment of the disease can be placed on a sure and sane footing.

VACCINE VIRUS AND CHLOROFORM.

During the epidemic of smallpox, in recent years, so much vaccine material was called for on several occasions that a sufficient amount of it was not on hand duly prepared for distribution. As a consequence, in some few cases, vaccine virus insufficiently glycerinated, that is, which had not been subjected for a sufficient period to the antiseptic action of glycerin, was distributed. As can be readily understood, this carried with it a certain danger of infection, because many of the micro-organisms in the vaccine material had not been destroyed. Sore arms were the result with an obscuration of the effectiveness of the vaccine material, since the mere occurrence of a deep scar does not by any means give evidence of successful protective vaccination, but rather of secondary infection.

There has been a growing impression for some time that if another agent besides glycerin could be employed, which without eventually impairing the efficiency of the vaccine material, would destroy all other germs present, it would be an important discovery and would fill a distinct want.

Such a material seems to have been discovered in chloroform. In a recent report, Dr. Alan B. Green, of the English government lymph laboratories, said: "Since April, 1903, the date of my preliminary note on this subject, the preparation of calf vaccine by the chloroform process has been carried on at these laboratories, and a large number of vaccines have now been treated by this method. These lymphs have been freed from their non-spore-bearing extraneous bacteria within a period ranging between one and eight hours after their collection from the calf and have, subject to the usual tests, been issued for general vaccination purposes about two weeks after collection. Their use has resulted in a large proportion of successful vaccinations."

This very favorable report has been confirmed by some experiments in the Health Department of Chicago, as reported in the recent bulletin of that Department. According to the crucial tests made in Chicago, chloroform-vaccine was used by the municipal health board physicians five days after it was removed from the calf. One day was required to prepare it, one day to ship, two days to test it bacteriologically, and one day to send it to the clinician who made the clinical test. Ten days later his report was that this chloroform vaccine material had given 100 per cent. of successful primary vaccinations. Besides the rapidity with which the vaccine may be prepared, there is another and decided advantage in that the length of time during which the vaccine matter remains active is considerably prolonged. Under the action of glycerin, foreign micro-organisms present are soon destroyed, but the organisms of vaccine are rendered inert after a time and, consequently, unused vaccine has to be withdrawn from the market. With chloroform, the action may be allowed to continue until all foreign micro-organisms are destroyed, and then no further action takes place. Consequently there is thought to be no deterioration of the vaccine material.

These are as yet only preliminary reports, although the tests to which the material has been subjected are distinctly sufficient to justify very hopeful conclusions. Vaccine material in its purest possible state, without admixture of any foreign living material, especially, is a supreme desideratum of modern times. Since the medical profession is insisting on the necessity for every individual being vaccinated, and since, as a consequence of this insistance, laws have been passed in most of the civilized countries of the world practically making vaccination compulsory, it is an absolute necessity that vaccine material should be prepared in such a way as to carry with it no danger except the infinitesimal risk involved in the vaccination process itself. The new agent seems to promise a notable advance along these lines, and, therefore, its possibilities should be exploited with the greatest care. Vaccine manufacturers may be depended on to be properly enterprising in this as they have been in the past, and the medical profession must be ready to weigh further demonstrations in the matter.

MEN OF SCIENCE.

THE third of the annual meetings of "Convocation Week" will be held in Philadelphia from December 27 to 31, in the ample buildings of the University of Pennsylvania. Twenty-five different scientific societies will combine to make that locality during that week the center of American philosophy and science. The associations of scholars which will be represented are the ten chapters of the American Association for the Advancement of Science with their more than four thousand members; the American Philosophical Association, Psychological Association, Physiological Society, Anthropological Association, Chemical Society, Folk-Lore Society, Physical Society, Society of Naturalists, Society of Zoologists (Eastern Branch), the Association of American Anatomists, the Association of Economic Entomologists, the Astronomical and Astrophysical Society of America, the Botanical Club of the A.A.A.S., the Botanical Society of America, the Entomological Club of the A.A.A.S., the Fern Chapter, the Geological Society of America, the Societies of American Bacteriologists, for Horticultural Science, for Plant Morphology and Physiology, for the Promotion of Agricultural Science, the Sigma Xi Honorary Scientific Society, the Sullivant Moss Chapter, and the Wild-Flower Preservation Society of America. The chapters of the American Association for the Advancement of Science represent, respectively: A, mathematics and astronomy; B, physics; C, chemistry; D, mechanical science and engineering; E, geology and geography; F, zoology; G, botany; H, anthropology; I, social and economic science; and K, physiology and experimental medicine.

This truly rather formidable list is given in full to emphasize the variety of learned and cultural interests which meet annually just after Christmas in some one of our important cities for mutual mental improvement and intellectual enjoyment. And these great meetings, characteristic of American democracy, give even more than that, for they allow former friends, schoolmates, colleagues, sundered by academic appointments and by other means, to meet under sympathetic conditions and where each one has for the few days left his burdens behind him that he may partake of the other, but unlike mental burdens of his fellows! These meetings afford the recreation which variety and a journey bestow, and no one better than the physician knows how a week or four days out of the middle of his busy winter would cheer his soul for the months to come.

It is often far too easy for the practitioner to make even himself believe that his "practice will not allow him to get away," that he "can't afford the time," etc. Observation shows that the men who accomplish most are not the "grinds" of the world and that proportionally to the mental difficulty of their pursuits the more thought there is in an occupation the more necessary is a degree of independence of routine and a fair proportion of recreation. It is on this substantial basis of physiology, that the conscientious physician owes it to his patients not less than to himself and his family to escape occasionally into an atmosphere at least different from that he daily breathes.

Now it would be natural at first for many medical men to say that at such a meeting they would be engaged in only what they need change from, namely, science. A glance over the list shows one, however, so large is the variety of interests concerned that the physician may indulge in the science in which he is an amateur with reason and with benefit. The American Association for the Advancement of Science welcomes new members from the medical profession, and offers them practically the whole range of science to choose from. Fortunate, the busy practitioner who has geology for a hobby and who, therefore, finds himself time every summer for a month in Nova Scotia or among the White Hills. Wise is the busy physician who, despite the jokes of his daughters and the sly reproaches of his neurasthenic women patients, builds up an herbarium of his own, collecting between Texas and Labrador. To the philosophically minded there is plenty to be heard at these meetings which would make his cortical neurones vibrate in a way to delight Forel himself, were not "the neurones" things of the past. The Anthropological Association and the Folk-Lore Society discuss matters of absorbing interest to every physician. None of these societies is apt to refuse membership to the medical graduate who applies, seriously intending to contribute to its advancement.

The monetary cost is small. The railroads furnish a round trip for one-and-one-third fares. The hotels pretend at least to reduce their rates. The entrance fees and the annual dues are nominal, and in most cases return rather more than

their value in literature. Thus every member of the American Association for the Advancement of Science paying the dues of three dollars a year, is entitled to the weekly magazine, *Science*, as the official journal of the Association.

One has much to gain and little, broadly speaking, to lose, if he attends these annual meetings held East or West for four days after each Christmas. Besides his personal gains (and his wife's, if he has one and she goes along), the physician has the pleasure of feeling that he is contributing to the interest and influence of science in America. This is no mean benefit when one considers the predominant part which science has taken, and is more and more largely taking in the development of our country and of the world. The practitioner of medicine, like other men, is apt to get into ruts from which it is a fact of general experience that the majority never escape. These enthusing meetings of the scientists of America offer one way out. It is not too late for many to join the large but harmonious scientific family party, at the University of Pennsylvania on the second day after Christmas. Physicians are apt to forget that with all their art, the practice of medicine makes them men of science—every one.

ECHOES AND NEWS.

NEW YORK.

Appointment of Dr. Pritchard.—Dr. W. B. Pritchard has been appointed Professor of Neurology at the Polyclinic Hospital and Medical School, to occupy the chair recently vacated by the resignation of Dr. B. Sachs.

Zoological Pitfalls.—The Middleton Goldsmith lecture of the New York Pathological Society was delivered at the New York Academy of Medicine, on November 30, at 8:30 o'clock, by Dr. Charles Wardell Stiles, chief of the Division of Zoology, Hygienic Laboratory, U. S. Public Health and Marine-Hospital Service. The subject was: "Zoological Pitfalls for the Pathologist." A full analysis of the lecture will be given later.

Pan-American Delegate.—Dr. Frederick Holme Wiggin has been appointed a delegate to represent the New York State Medical Association at the coming meeting of the Pan-American Medical Congress, to be held in Panama.

Sanitary Conference.—The Fourth Annual Conference of Sanitary Officers, under the direction of the State Department of Health, will be held in the Assembly Chamber of the Capitol at Albany, December 15 and 16, 1904. For the purpose of securing a uniform system of sanitation, and increasing the efficiency of local boards of health, this department is anxious to secure the attendance at the conference of as many health-officers and registrars as possible. Under Section 21 of the Public Health Law, local boards of health are authorized to allow the reasonable expenses of health-officers in "going to, attending and returning from the Annual Sanitary Conference of Health Officers."

Report of Presbyterian Hospital.—A summary of the work done at the above institution during the past two years has just been issued. Especial prominence is given to the financial statement which states the great need of more money to carry out plans for more efficient service. The cost per day per patient was $2.48⅓, as compared with $2.50⅔ during the previous year. The actual cost to the hospital of free treatment during the year was $150,110.66, as compared with $149,984.43 for the previous year. The most important event in the hospital life of the past year has been the opening of the Florence Nightingale Hall, the school for nurses, on Seventy-first Street, which, fully equipped, cost $410,000. It was given anonymously by one of the managers. Transfer of the nurses to their new building has vacated the ward space in the hospital previously occupied by them. This would provide more than 100 beds for that number of new patients. These wards must remain closed and the beds unoccupied until current and continuing means for their support are provided.

Rockefeller Research Laboratory.—The cornerstone was laid last week for the Rockefeller Institute, which was founded by John D. Rockefeller, Sr., with an initial endowment of $200,000, since increased to $1,200,000, and the promise of more when needed. The institute was founded for pure research into the cause of disease. For several months this research has been carried on by students in this city and other cities. Dr. Simon Flexner, the chairman of the governing board of the institution, has gathered about his a carefully selected body of men, all of whom are known in some branch of medical science. The trustees a year ago bought a site on a tract of land lying along the East River from Sixty-fifth to Sixty-eigth street and extending back to Avenue A. This tract belongs to Mr. Rockefeller. The site was purchased from him with the money he had supplied, and is not an additional gift to the institution. The cornerstone laid in Sixty-fifth Street near Avenue A is for a laboratory in which special investigations of the bacteria of disease will be carried on. The stone was laid by Dr Flexner, assisted by the other officers of the institute, T. M. Prudden, professor of pathology at the College of Physicians and Surgeons; Dr. L. Emmett Holt, secretary of the institute, and Dr. C. A. Herter, treasurer of the institute and professor of pharmacology at the College of Physicians and Surgeons. Within the cornerstone were placed a photograph of Mr. Rockefeller, a history of the organization of the institute, copies of the current medical magazines and daily papers. There will be a public dedication ceremony when the building is completed. A small hospital will be built in the next two years. The few patients admitted to this hospital will receive the best of care and benefit of the most recent advances in medical science, but they will be used as subjects in the study of the causes of disease for which the institute has been endowed. While waiting for the new building the Rockefeller Institute has temporary quarters at Fiftieth Street and Lexington Avenue, where experiments are being carried on under the direction of Dr. Flexner.

National Mosquito Extermination Society.—The second annual convention of this Society will be held in Manhattan and Brooklyn on Thursday and

Friday, December 15 and 16, 1904. The public is invited to attend. The program is as follows:

First Session, December 15, 2:30 P.M. To be held at New York Aquarium, by courtesy of the Director, with the approval of the New York Zoological Society. (The Director will provide exhibits of living specimens showing the hatching of mosquitoes, and the various small fishes important as the destroyers of mosquito larvæ. He is now making experiments with a view to showing the comparative value of certain species of fishes in this connection. The Aquarium is easily reached by all surface and elevated lines to Battery Place.) Greetings from Major Ronald Ross, M.D., of Liverpool, England, recipient of Nobel Prize for discoveries of relation between certain mosquitoes and malaria. "Criminal Indictment of the Mosquito," submitted by Frank Moss, Esq., Counsel for Society for the Prevention of Crime. Submission by the audience of proposed Essential Questions to be asked later of the Advisory Board of Entomologists; their answers to be unified into a "Creed on Mosquitoes."

Second Session, December 15, 8 P.M.—Dr. L. O. Howard, Chairman; joint Session with Brooklyn Institute of Arts and Sciences, to be held in the Art Rooms, 174 Montague Street, Brooklyn. Paper by Col. Wm. C. Gorgas, M.D., Asst.-Surg.-Genl., U. S. A., in charge of "The Sanitation of the Panama Canal Zone," on this work. Address by Dr. E. Porter Felt, N. Y., State Entomologist, "Diversities Among New York Mosquitoes," illustrated by a large number of original lantern slides, representing various species in all stages and their differences.

Third Session, December 16, 2:30 P.M.—In conjunction with the Brooklyn Institute, in Hall, first floor, 502 Fulton Street, Brooklyn. Remarks of Chairman, Dr. John B. Smith, New Jersey. Representation of the Public Health and Marine Hospital Service. Dr. Walter Wyman, Surgeon-General, Dr. M. J. Roseneau, Director Hygienic Laboratory, Washington, subject: "Methods of Examination and Dissection of Mosquitoes for Parasites," (illustrated with many striking lantern views). Address by Dr. Thomas Darlington, Health Commissioner: "What New York City is Doing and Might Do toward Mosquito Extermination."

Third Session, December 16, 8 P.M.—By courtesy in the Hall of the American Institute, Berkeley Lyceum, 19 and 21 West Forty-fourth Street, Manhattan. Remarks by the President. Address by Dr. Quitman Kohnke, President Board of Health, New Orleans, La., on "The Mosquito Question." Illustrated by colored lantern-slides made from drawings, photographs, micro-photographs and diagrams, and by moving pictures, including mosquitoes in life and in asphyxiation by oil on water. Paper by Cornelius C. Vermeule, C.E., Consulting Engineer of the New Jersey State Geological Survey, etc., on "The Relation of Mosquito Extermination to Engineering and Public Improvements."

PHILADELPHIA.

Reception to Dr. Chapin.—The completion of fifty years' work among the insane was the occasion of a testimonial dinner to Dr. John B. Chapin, Superintendent of the Pennsylvania Hospital for the Insane, on December 1. The dinner was given in the Clover Club room of the Bellevue-Stratford and was attended by more than 75 physicians. Among the guests were the assistant physicians in the hospital, the board of managers and the trustees. A large oil painting of himself was presented to Dr. Chapin as a testimonial of the regard felt for him by the profession. The presentation was made by Dr. Henry M. Hurd. Dr. E. N. Brush presided at the meeting and the following toasts were given: "Dr. Chapin and His Fellow Physicians," Dr. James C. Wilson; "The Law and the Doctor," Mr. James M. Beck; "The Physician and the Christian Gentleman," Rev. Stephen W. Dana, and "The Pennsylvania Hospital," Mr. James T. Shinn. The esteem in which Dr. Chapin is held by those outside of the medical profession is well shown by an editorial in the Philadelphia *Press*. In speaking of the revolution in the care of the insane, started by Dr. Chapin, it says the entire treatment and housing of the insane has been changed. "It has substituted separate small buildings for the large palatial structures once built. It has recognized the vital difference between the chronic and curable insane. It has relied upon a healthy environment and opportunities for work as equal in importance with medical treatment. Above all, it has looked upon the insane not as those set apart from their fellows but as patients, requiring indeed special precautions but demanding also the medical care, the individual treatment and the special individual environment, required by all the ill and ailing. This treatment substituted the hospital for the asylum and the cottage for the great dormitory. It brought greater comfort for the chronic and a greater percentage of cures for the curable. In this advance, which he began almost alone, nearly forty years ago, Dr. Chapin has steadily led, and the work which he has done in this city, at the head of one of its most important institutions, is one of the many claims of Philadelphia to be the center of the medical advance."

Nurses' Home Presented to Hospital.—Mr. and Mrs. Horace Brock, of Philadelphia, have presented to the Good Samaritan hospital, of Lebanon, a nurses' home costing $7,500.

Special Lectures for the County Medical Society.—The second in the series of special lectures for the Philadelphia County Medical Society will be held December 21, at 8:30 P.M. Dr. William G. Spiller will speak on "The Diagnosis of Tumors Implicating The Intracranial Portion of the Visual System," and Dr. Allen J. Smith on "Terminal Atony of the Large Intestine."

The Use of Methylene Blue in Malarial Fevers.—At the County Medical Society, November 9, Dr. H. C. Wood, Jr., read a paper on this subject and reported the use of the above drug in seven cases of malaria. One was complicated by typhoid fever and the effect of the methylene blue cannot be judged. Of the remaining six, three were tertian and three quotidian in type. In all six there was cessation of symptoms and disappearance of fever as a result of treatment; in four there was at least one distinct rise of temperature after the drug was begun. One relapse occurred but readily yielded to treatment. Altogether the results were extremely gratifying. Wood believes, from these cases and the reports of many more in the literature, that in methylene blue we have an antiperiodic that rivals quinine in power and which in many cases is to be preferred to that alkaloid on account of its freedom from unpleasant by-symptoms. He employs the drug simply by giving two or three grains every three hours for a period of a week

to ten days and then making the withdrawal a gradual one. The failure to continue the treatment over a period of several weeks has been the cause of many of the relapses recorded. In answer to the point raised in the discussion that methylene blue was a sedative, Dr. Wood said he observed no signs whatsoever of this action of the drug in his cases.

University of Pennsylvania Notes.—The completion of registration figures for the University of Pennsylvania shows that the dental department is the most cosmopolitan of all the schools. A few of the countries represented are China, England, France, Germany, Russia, New Zealand, Switzerland, Africa, Japan, Holland, and the East and West Indies. Nearly 20 per cent. of the 358 students enrolled are subjects of Great Britain, thirty-three of them being from Australia. The school prints annually a catalogue in several foreign languages. The department has in its post-graduate school Dr. T. Okumura, professor of dental anatomy and histology in Tokio Dental College. He is the author of several Japanese works on dentistry, and has secured a two years' leave of absence, to be spent here in studying the modern methods of the science. The old medical laboratory has been renovated and will now be known as the "Robert Hare Laboratory of Chemistry," to be used for all medical students in their study of chemistry. The faculty of the Wharton School has arranged for a series of lectures on "The Selection of a Profession."

Pennsylvania State Medical Examination.—The official report of the Pennsylvania State Medical Board shows that the graduates of the University stood second in the number of successful candidates at the recent State Board examinations. The Women's Medical College of this city made the highest average.

CHICAGO.

Resignation of Dr. Woelfel.—Dr. Albert Woelfel has resigned his position in the Memorial Institute for Infectious Diseases, Chicago, to accept an appointment in the Department of Physiology, of University of Chicago.

Inspect New Hospitals.—The Cook County Hospital Advisory Committee recently inspected the new hospital for contagious diseases and the new hospital for children, which, it is said, will not be finished until January. Besides the members of the Hospital Committee, members of the other advisory committees of the County, County officials, charity workers and many others were invited and participated in the inspection.

Delay Merit Test for Physicians.—Although the civil service examination for candidates for the attending staff of the Cook County Hospital was announced for December 1, it has been in effect indefinitely postponed, pending an opinion of the County Attorney, to whom the question of the legality of the test has been referred by the Commission. The sentiment of those who favor the examination is that the matter has already been decided. When President Foreman of the County Board of Commissioners vetoed the action of the County Commissioners in rescinding their former action in favor of the examination he presented with the veto an opinion from the Assistant County Attorney, on which his veto was based.

A State Health Board Propaganda.—We have received from the State Board of Health of Illinois a large well-printed poster issued by them and distributed throughout the State to be the means of educating the people as to the dangers of smallpox and that it is prevented by vaccination. It shows a number of graphic illustrations of patients suffering from smallpox and is accompanied by straightforward text as to the methods of vaccination. We should like to see more posters of this kind distributed throughout rural communities not only regarding smallpox but other communicable diseases as well. Here is a field now being let slip my many health departments, to be cultivated by manufacturers. The guinea-pigs and exhibition of sera of Mulford's, now shown in many of the large cities, are well devised and instructive. Propagandas of this kind are worth while and money spent in this way is as much more productive of good results than by the sending of health board statistics to readers who are not interested. We commend to the National Tuberculosis Association this movement as a useful piece of detail to be followed and improved upon.

GENERAL.

Harvard Medical School Buildings.—Work on the new Medical School buildings at Brookline has been progressing steadily this fall. Of the five structures, that for the Hygiene and Pharmacological Departments is nearest completion, the rooms being already plastered and ready for rough flooring. The Bacteriological and Pathological Building is ready for plastering and the roofs of the buildings for Physiology, Physics and Chemistry and for Anatomy and Histology, are all but completed. The Administration Building is the least advanced of the five, since it was desired primarily to put the laboratory buildings in condition to withstand the winter. Whether or not the buildings will be completed next summer, according to the terms of the contract, depends upon the severity of the coming winter.

Free Service of Dental School.—During the past six years the Dental School has maintained a free service for the sick poor of Boston, and has been prepared at all times to send a dentist to relieve such persons, either at their own homes or in the hospitals. This service has been recently extended in order to be of greater efficiency than heretofore. Th school is now able to send one of its graduates, registered by the State board of registration, to relieve the pain of any sick poor person who is in need of immediate dental treatment. More extended treatment is postponed until the patient is able to visit the infirmary of the Dental School.

Crippled and Deformed Children in Massachusetts.—Governor Bates sent to the executive council to-day the appointment of these five trustees of the Massachusetts School and Home for Crippled and Deformed Children, the establishment of which institution was authorized by Chapter 446 of the Acts of 1904: Dr. Edward H. Bradford, of Boston (chairman); William Endicott, Jr., of Beverly, Hon. Alfred S. Pinkerton, of Worcester, Dr. William A. Morrison, of Boston, and Leonard W. Ross, of Canton. The act under which these trustees are appointed empowers them to purchase land and erect buildings for a home to hold not less than three hundred children, officers, employees and attendants, and to furnish and equip the same at a maximum cost of $300,000, the plans to be subject to the approval of the governor and council. The trustees are to receive no compensation for their services, but shall be reimbursed for all expenses actually in-

curred by them in the performance of their official duties. The State Board of Charity is to have general supervision of the institution, and may, when so directed by the governor, assume and exercise the powers of the trustees in any matter relating to the management thereof.

Suffolk District Branch Massachusetts Medical Society.—The last meeting of this branch of the Massachusetts Medical Society, in conjunction with the Boston Medical Library, was held November 30, 1904, at the Library. The subject for discussion was "Ptosis of the Abdominal Organs, with Especial Reference to Ptosis of the Kidney." Dr. P. B. Harrington was in the chair.

Dr. M. P. Southwick first spoke on "The Importance of Keeping in Mind Ptosis of the Viscera, in Considering Treatment of the Kidney." He mentioned various conditions which had been given as causes of ptosis of the kidney; childbirth, tuberculosis, trauma, etc.; but said it was necessary to go back of this to a neuropathic condition, of low nerve power, in which the point of least resistance was attacked, whether this be a retroverted uterus, cardiac or stomach neuroses, flatfoot or other orthopedic conditions, or a movable kidney. In his private practice, out of sixty-eight cases with a movable kidney, half that number had retroverted uteri. Many of his cases showed no symptoms of the kidney conditions. Others only general neurasthenic symptoms. He mentioned the rarity of real renal colic, and of cases of movable kidney, where the symptoms seemed to point definitely to that region.

Dr. W. H. Smith spoke on "Experience with Abdominal Supporters." He described two kinds of belts; one a plain abdominal band, which he had used but little, the other an accurately fitting, padded, corset-like belt. He then described in detail two cases which had been greatly benefited by such a belt as last described, and then another case not improved because the belt was put on with the patient standing, thus increasing rather than diminishing the pull on the kidney. In cases of general neuroses he did not advise the belt, nor in patients with gastroptosis. He emphasized the fact that belts would, in his opinion, do good only with the intelligent cooperation of the patient and in carefully selected cases.

Drs. Frank Balch and James Torbert next described the results of operation on movable kidneys at the Massachusetts General Hospital from 1890 to 1904. Out of 92 cases 41 replied to letters sent out, and out of these 28 were relieved and 13 not. The majority could give no definite cause for their condition; many attributed it to childbirth, a few to trauma; 86 were females, 6 males. In many cases additional operations had been done later on the gall-bladder or the appendix, rendering their reports unreliable. They spoke of the necessity of carefully choosing cases with real kidney symptoms. In such cases an operation might do good, in cases of general enteroptosis it would not.

Dr. R. G. Gordon gave a report of 17 cases from the Boston City Hospital during the last ten years, out of which he had had a personal interview with ten. They were all women, but of these two were operated on later for gall-stones; five were definitely cured and able to do their work without the slightest trouble, the rest were either unrelieved or only slightly improved.

In the discussion which followed these papers, Dr. H. D. Chadwick, of Waltham, spoke on the symptoms of movable kidney, which, in his opinion, required surgical relief. He had no success with belts, and did not believe a belt could pad the kidney. Out of twenty operations he considered only three to be failures.

Dr. A. T. Cabot said that comparatively little was as yet known as to the cause and symptoms of movable kidneys. The gravity of the symptoms did not in the slightest accord with the amount of movability of the kidneys, often quite the reverse. He thought it depended on the tolerance of the central nervous system to little irritations. He spoke of the anatomical conditions present, that the short right renal vein might be more easily shut off than the longer corresponding renal artery, thus causing a chronic congestion. He thought that an operation done early was far more apt to benefit the patient than a late one, as secondary changes due to chronic passive congestion were then not given a chance to take place. Silk he considered better for the operation than any soluble suture material. He fastened the kidney just high enough so that it was not pressed upon by the liver.

Dr. Paul Thorndike thought that the large numbers of cases done and reported by men of little surgical experience in the past accounted for the large per cent. of failures. Out of 272 cases 91 reported in the out-patient department; 112 had movable kidneys without any symptoms. In many cases symptoms are coincident with and not the result of a movable kidney. He had no success with belts.

Dr. A. K. Stone spoke of the confusion of terms as regards this subject, and the necessity of distinguishing between the palpable kidney, which is almost a normal condition, and a real movable kidney. He mentioned the occurrence of acute cases due to extra strains onthe nervous system as on the back where the kidney was already movable, but had up to then given no symptoms. With belts he had good success where an operation advised had been refused. He thought the belt must be very carefully fitted and treated as any complicated orthopedic apparatus.

Dr. W. B. Conant spoke of the position of the kidney in the body and how to preserve this natural condition on operation, also on the frequency of some trouble with the appendix in these cases. He used the lateral incision for this operation, thus exploring the entire abdomen.

Dr. R. C. Larrabee spoke of his out-patient experience with these cases and mentioned that in a large number of patients found to have movable kidney, the symptoms were as common in those who did not know they had a floating kidney as in those who did.

Drs. Stevens, Lund and Gay also spoke on this subject.

At a clinical meeting of the Medical Board of the Massachusetts General Hospital held December 2, 1904, Dr. F. B. Harrington spoke on angioneurotic edema, going carefully over the etiology and pathology of this condition, especially as regards the abdominal crises occurring during the attack. He mentioned its hereditary tendency; its relation to the other neuroses as urticaria, purpura, etc., and gave in detail the symptomatology of the abdominal crisis, and then described a case where a laporatomy had been done and a localized edematous swelling of the gut found near the cecum.

In the absence of Dr. R. H. Fitz, his house officer, Dr. Floyd, demonstrated a case of typhoid hematoma involving the rectus muscle occurring in a very severe case of enteric fever when restraint had been necessary by a sheet across the abdomen. The differential diagnosis between this and phlegmon was carefully considered.

Dr. George Waterman read extracts from a paper on cases illustrative of the differential diagnosis between epilepsy and hysteria.

Dr. C. S. Scudder demonstrated the Connell suture, as used by him in gastric and intestinal surgery.

Dr. W. H. Smith demonstrated for Dr. C. S. Shattuck relaxation of abdominal muscles of patient examined in a warm bath, and cited cases where this procedure had been of distinct advantage as an aid to diagnosis.

Dr. Fred Lord read a paper on Flies and Tuberculosis. He went over the literature of this subject, and then described his own experiments on flies fed on tuberculous and non-tuberculous sputum, with subsequent examination of the excreta as found in fly specks and of the intestinal contents themselves.

Dr. A. K. Stone read a paper on the "Value of X-ray in Phthisis," showing where he found it of use and how very misleading it was in certain instances.

American Academy of Ophthalmology and Oto-Laryngology.—This Society will hold its next meeting in Buffalo on August 23, 24 and 25, 1905. President, H. W. Loeb, St. Louis, Mo.: Secretary, George F. Suker, Akron, Ohio.

Pollution of Inland Waters.—A review of the laws forbidding the pollution of inland waters in the United States, writes *Science*, has been prepared by Mr. Edwin B. Goddell for the United States Geological Survey. It is published as No. 103 of the series of Water-Supply and Irrigation papers. Mr. Goodell's purpose has not been to prepare a complete work on water pollution for the use of members of the bench and bar, but rather to put into the hands of public officials, legislators, water companies, manufacturers, farmers and others interested in the subject, a guide for their action, and to furnish references to the sources from which a more exhaustive knowledge of the subject may be obtained if required. No attempt has been made to present a detailed statement of the entire law against water pollution as it exists independently of statutes, but the broad legal principles under which antipollution statutes become operative are explained and important court decisions are quoted to show authority for various deductions. These principles and decisions have been classified and are presented in three groups: (1) The rights of riparian owners to pure water as against one another; (2) the rights of the public (as distinguished from individual owners) to have inland waters kept free from pollution by riparian owners or others; (3) the conditions under which, and the extent to which, public municipalities may use inland waters in the disposal of sewage matter from public sewers. The statutes enacted in various States are classified according to their general scope and an opportunity is thus afforded to compare their effectiveness and desirability. In some states there is nothing more than a simple provision making it a crime to poison wells and springs, while in others elaborate provisions have been made to check and, so far as possible, absolutely prevent all pollution of all waters by the refuse products of animal life or the waste of human industry. In citing the statutes, Mr. Goodell has grouped the States together logically to show the stage of growth in sanitary education at which each has arrived. It is hoped that the publication and distribution of this paper will help to bring about a general apprehension of correct principles upon the important subject of water pollution.

OBITUARY.

Dr. Jacob P. Bixler, a well-known physician, died at Carlisle, Pa., last week from paralysis. He was sixty-three years old. In 1866 he was graduated from Jefferson Medical College, Philadelphia. He was a member of the Pennsylvania State Medical Society, and for many years he was president of the Carlisle school board.

Dr. William E. Carroll, of Newark, N. J., died December 2, at St. Michael's Hospital in that city, of pneumonia. He was a member of the staff of the hospital and for years had a large private practice. Dr. Carroll was born in Newark fifty-seven years ago.

Dr. William F. Cushman, for many years a practitioner of medicine in New York City, died last week at his country place, at Ridgefield, Conn., aged sixty-six years. He was a member of a well-known family, which for many generations lived in the Chelsea village district of Manhattan. Dr. Cushman was graduated from Columbia University and from the College of Physicians and Surgeons, and was for many years treasurer of the New York Academy of Medicine.

Dr. Leonard F. Pitkin, surgeon to the Interborough Company, New York City, died last week at St. Luke's Hospital. Dr. Pitkin was taken ill last spring, and had to retire temporarily from the practice of his profession. He spent most of the summer in the country, and returned two months ago apparently much improved. Tuesday he became so ill that he was removed to St. Luke's Hospital. He was suffering from kidney disease. Dr. Pitkin was born in Hartford, Conn., in 1858. His family is one of the oldest and most prominent in New England. He came to New York twenty-five years ago, and built up a large general practice, being connected as medical adviser with several corporations. He was the physician who attended all subway cases since that work began.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BIRTHDAY HONORS—THE QUEEN OF PORTUGAL—THE HEALTH OF THE KING AND THE PRINCE OF WALES—A NATIONAL COLLEGE OF PHYSICAL EDUCATION—THE NATIONAL LEAGUE FOR PHYSICAL EDUCATION—THE UNIVERSITY OF LONDON AND RACE DETERIORATION—DEATHS IN THE PROFESSION.

London, November 19.

The list of birthday honors issued on November 9 contains the names of only three or four members of the medical profession, not one of which probably has reached your side of the Atlantic. The best known of them is Mr. Shirley Murphy, Medical Officer of Health for the County of London, a meritorious official who has somehow failed to do all that was expected of him when the new administration of London, of which he is a part, came into being. He is a sound hygienist, but somehow gives the impression of irresolution in action and general indefiniteness of opinion. Hence his services, valuable as they are, have always been imperfectly appreciated by the Council which he serves. His salary ($6,250 a year) is little more than half that of the Chief Clerk, the architect, the engineer and the valuer. The title has doubtless been got for him by some friend at Court by way of compensation for the inadequacy of his emolument. The only other new knight of any note in the medical world is Dr. William Japp Sinclair, Professor of Obstetrics and Gynecology in the University of Manchester. His title is probably a recognition, not so much of his scientific merits, which are not such as to make it inevitable that the King should delight to honor him, as of the part which he has taken in

promoting the higher education and registration of midwives.

The Queen of Portugal is here and her presence has naturally brought to life again the old fable that she is a doctor of medicine. This was officially denied some fifteen years ago in the *British Medical Journal* by the Portuguese Minister to the Court of St. James, who stated that although Her Majesty had always taken a great interest in medical matters she had never gone through a formal course of study. The legend is, however, too useful for journalists willingly to let it die, and it will doubtless be kept for use whenever circumstances make its revival appropriate.

So many official and "officious" statements have lately been made as to the King's health that persons of suspicious temper might almost be tempted to think that those about His Majesty protest too much. We are assured in inspired articles that he is in the most vigorous health, and that he owes this to his scrupulous care in the matter of drink and diet. It is likely enough that since his appendicitis scared him he has been more moderate, but the officers of his Life Guards have not forgotten the Gargantuan trencher feats which their royal guest performed for their edification whenever he condescended to dine with them. These occasions were known among them by the significant name of "gobble nights." It is recorded that Louis XIV. once complained that he had almost had to wait (J'ai failli attendre!). It was distinctly understood that Edward VII. must not be kept waiting at table. His plate, therefore, was never allowed to stand empty before him, even for a moment, and his glass had to be constantly refilled. Mere men of mold could not keep pace with him. He once assured a distinguished physician, who was called in rather behind the backs of the regular attendants, that he did not drink much—not, at any rate, like his brother, the Duke of Saxe-Coburg. That may well have been, for the Duke, when at sea had sometimes to be kept out of the way of visitors. Our temperate sovereign, however, has been known to drink seven different kinds of wine at one repast, to say nothing of liqueurs, chasse-cafes and whisky afterward. If it be true, therefore, as now stated that "of wines he partakes most sparingly," one can only infer that he has made the discovery that there are limits even to the tolerance of a royal stomach.

Rumors have found their way into certain newspapers that the Prince of Wales is suffering from consumption, and that this fact supplies the explanation of his sea voyages. The statement has, of course, been met with the usual official contradiction. People remember, however, that in 1902 a statement made in *Reynolds' Newspaper* to the effect that the King was seriously ill, and contradicted in the same way, was verified almost immediately by the postponement of the coronation ceremony and the operation for appendicitis. It may or may not be significant that the statements about the Prince of Wales have been published in the same paper. The members of our royal family are nearly all unwholesome looking. Bismarck opposed the marriage of the late Empress Frederick with the Crown Prince of Prussia on the ground that she came of a stock which he coarsely but not untruly characterized as "those scrofulous Guelphs." To those familiar with the appearance of the Prince of Wales there is nothing improbable in the suggestion that he is tuberculous.

A conference was held in London on November 16 to consider a proposal to introduce into England the methods of physical training taught at the Royal Central Institute of Sweden. There students go through a course of instruction extending over three years in the theory and practice of massage. The promoters of the scheme hold that massage has been misused and misunderstood in this country, and that it is necessary to place it on the same footing as, for instance, pharmacy. At the conference Miss Theodora Johnson, principal of a Swedish Institute at Bristol, advocated the adoption of a scheme of national physical training similar to that which exists in Sweden. In order that the poor might learn the elementary rules relating to the care of the body she urged the appointment of a large number of itinerant lecturers who should go about preaching the gospel of health. Lord Londonderry, President of the Board of Education, who was present, said the report of the Committee on Physical Degeneration showed how necessary it was that physical education should be brought within the reach of every child in the country. He promised that the report should receive the most careful consideration from the department of which he is the head. While declining to give any pledge in the name of the Government, he said the proposal to establish a great central organization for the promotion of physical education must commend itself to all. He added, however, that the details of the scheme were so varied that it was impossible for him to express approval without fuller examination. The scheme received the support of Sir William Broadbent, Sir Lauder Brunton and Sir William Church, President of the Royal College of Physicians of London. The last-named moved a resolution that steps should be taken to establish in the United Kingdom a national system of physical education, and that the conference should form itself into an association for the purpose of pressing proposals to that effect on the Government. The motion was seconded by Sir Lauder Brunton and carried "unanimously." So say the newspapers. The fact is, however, that only four persons out of a meeting of fifty, or thereabouts, were allowed to vote. Their unanimity, therefore, is not so wonderful as it might seem. The Bishop of Bristol, who presided at the conference, stated at the outset that only persons who had been invited would be allowed to vote. In plain English, the meeting was packed. Why this curious precaution was adopted I cannot say, but it looks as if the promoters were afraid of opposition.

As Sir Lauder Brunton is the Secretary of the National League for Physical Education and Improvement, it is not improbable that both the College and the League are in reality parts of one movement. According to him the first aim of the League is to coordinate all existing societies of kindred aim, including temperance associations, societies for the teaching of cooking, housekeeping and the feeding of children, athletic clubs, drill associations, cadet corps, boys' brigades, rifle clubs, volunteer corps and girls' clubs. The League further proposes to promote the establishment of gymnasiums and swimming baths for young people among the working classes who cannot afford to join tennis, cricket and football clubs. Special attention will be given to the physical training of women and girls. Brunton points out that the working women in towns very often marry at too early an age with no knowledge

how children should be fed. Often they go out to work to supplement their husbands' scanty earnings, and when the baby comes they are too weak or too busy to give it proper attention. The mortality of children under one year is appalling. Even among children under five years it is far in excess of what it ought to be. Of those who survive many grow up weakly, with constitutions permanently damaged. They go to school insufficiently fed. Their opportunities for play and physical development are far too few. All this is to be reformed. In a word, the aim of the League is the physical regeneration of the nation. It is hoped that when thoroughly organized it will be able to work through branches. Each branch should furnish instruction to the people on the laws of health generally. Girls, says Lauder Brunton, should be taught methods of cooking and housekeeping, and mothers instructed in the care of children. Physical exercises and opportunity for open-air games should be given to both boys and girls. In towns the mayors and corporations should be induced to take part in the organization. There should also be a committee of ladies to supervise the instruction of mothers and the care of children. Part of the work of the League will be to initiate changes in existing laws with a view to the promotion of physical efficiency.

In connection with the subject of the deterioration of the race it may be mentioned that at a meeting held on October 20, the Senate of the University of London accepted an offer from Mr. Francis Galton, F.R.S., to endow a Fellowship in the University for the promotion of the study of "National Eugenics," which he defined as "the study of the agencies under social control that may improve or impair the racial qualities of future generations, either physically or mentally." The person appointed to the Fellowship will be required to devote the whole of his time to the study of the subject, and in particular to carry out investigations into the history of classes and families, and to deliver lectures and publish memoirs on the subject of his investigations. The endowment is sufficient to provide not only for the Fellowship, but also for the salary of an assistant, and for the general expenses of the contemplated work, which it is intended to locate in one of the colleges or other institutions connected with the University. Mr. Galton, who is nearly ninety years of age, is a cousin of Charles Darwin. He is a past president of the Anthropological Institute and is well known to those who pursue, what the poet calls, the proper study of mankind, as the author of works on hereditary genius, Englishmen of science, their nature and nurture, natural inheritance, identification of individuals by fingerprints, and numerous other writings.

Herbert William Allingham, one of the busiest surgeons of the day, has found the strenuous life too much for him, and took his quietus a week or two ago at Marseilles, not with a bare bodkin, but with a hypodermic needle. He was only forty-two years old, and was successful beyond the dreams of the average British surgeon, holding appointments at court and being recognized as one of the best operators of the day. His speciality was the rectum, a field of surgical enterprise which was cultivated to good purpose by his father, who is still alive in retirement. The elder Allingham was once moved by the ambition to fill a seat in the Council of the College of Surgeons, which is looked upon here as the Sanhedrim of Surgical Israel. When the result of the poll was declared his coachman was heard to ask another Jehu waiting at the gate of the College where his master stood on the list. "At the bottom," was the reply. "Ah," said the coachman meditatively, "that's where he always is!" Young Allingham had a great charm of manner, and was accordingly very popular in society. He could talk about anything. But on one point, says an admiring scribe in one of our most icteric newspapers, he was adamant. "In ordinary society, though half a dozen persons present might be his patients, he was dumb about his work, and even his polished courtesy would give way before persistent questioning about professional matters." Surely there could be no more maladroit compliment to a surgeon than that he did not choose diseases of the rectum as a subject of conversation in mixed society. He might as well be praised for not having entertained the company by giving demonstrations on the half-dozen patients present. Allingham is succeeded in the post of surgeons to the royal household by Mr. Anthony Bowlby, of St. Bartholomew's Hospital, a surgeon who has proved his fitness for attending on royal personages by operating on the Princess Victoria of Schleswig-Holstein for appendicitis.

Another medical notable who has recently passed away is Dr. Charles Douglas Fergusson Phillips, author of a work on materia medica and therapeutics, which once had a considerable vogue. He was for some time lecturer on these subjects at Westminster Hospital, and examiner in the Universities of Aberdeen, Edinburgh and Glasgow. He was, I believe, originally a homeopath, but found professional salvation. Perhaps the greatest achievement of his life was the extraction of $80,000 from a railway company some years ago as damages for an injury which caused only temporary disablement.

AUENBRUGGER OR AVENBRUGGER?

To the Editor of the Medical News:

Dear Sir:—The name of Auenbrugger appears in literature spelled "Au," and sometimes "Av," these variations occurring in such authoritative writings as the following:

"Dictionnaire Historique de la Médecine Ancienne et moderne, 1828. Auenbrugger (Leopold) Né à Graetz dans la Styrie le 19 Novembre 1722.

Dictionnaire Encyclopédique des Sciences Médicales. "Auenbrugger (Leopold)—Dans le commencement de l'Anné 1761 paraissait à Vienne en Austriche une brochure etc., etc. Dans sa préface, dateé du 31 Décembre 1760 l'auteurs exprimait ainsi.

Encyclopedia Britannica 1875. "Avenbrugger or Auenbrugger, Leopold, a physician of Vienna. . . . He was born in Grätz in 1722 and died 1809."

In gathering material for the historic portion of an article on cardiac disease I fell into the error first made by Corvisart, who is probably responsible for this confusion, of spelling the name "Av." In conversation with Dr. Dock, of Ann Arbor, he called my attention to this error and I took the first opportunity of consulting an original copy of the "Inventum Novum," in the Surgeons-General Library at Washington, as I had not been able to procure one in the Library of the New York Academy of Medicine.

The following is an exact copy of the title page of an edition dated 1761, the year of the first publication:

LEOPOLDI AUENBRUGGER
MEDICINÆ DOCTORIS
IN CÆSAREO REGIO NOSOCOMIO NATIONUM HISPANICO MEDICI ORDINARII
INVENTUM NOVUM
EX
PERCUSSIONE THORACIS HUMANI
UT SIGNO
ABSTRUSOS INTERNI
PECTORIS MORBOS
DETEGENDI

(Printers Mark)
LABORE ET FAVORE

VINDOBONÆ,
TYPIS JOANNIS THOMÆ TRATTNER, CÆS. REG. MAJEST. AVLÆ TYPOGRAPHI.
MDCCLXI

In books printed as late as the seventeenth century two "V's" were used for "w" there being no such letter in the older fonts. The letters were sometimes crossed thus W. "U" and "V" were also interchangeable, as appears in lexicons published as late as 1840. It is not surprising then that Corvisart, in translating Auenbrugger's "Inventum Novum," should have introduced the spelling "Av" as shown by the following copy from a first edition:

NOUVELLE MÉTHODE
POUR RECONNAITRE
LES MALADIES INTERNES
DE LA POITRINE
PAR LA PERCUSSION DE CETTE CAVITÉ
PAR AVENBRUGGER

Medecin ordinaire de la Nation Espagnole dans l'Hopital impérial, a Vienne en Autriche
OUVRAGE TRADUIT DU LATIN ET COMMENTÉ PAR J. N. CORVISART
(*Titles*)
Insonvêre cavæ.....
Virg. Æneid
A PARIS
DE L'IMPRIMERIE DE MIGNERET
1808

The spelling Auenbrugger should be retained as this identifies the great discoverer with Germany (born at Grätz) which would not be the case with the spelling "Av." Very truly,

C. N. B. CAMAC.

108 East Sixty-fifth Street.
NEW YORK, November 21, 1904.

Treatment of Tuberculous Laryngitis.—To relieve the dysphagia in this condition the following tablet may be advised:

℞ Anæsthesin. 3i (4.0)
Pulv. altheæ. 3i (4.0)
Pulv. acaciæ. .....
Pulv. glycyrrhizæ. ..... aa q.s.
Fiat tabulæ No. L.
Hold in mouth until dissolved.

SOCIETY PROCEEDINGS.

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.[1]

Eighth Regular Meeting, held October 19, 1904.

The President, S. J. Meltzer, M.D., in the Chair.

Members Present.—Burton-Opitz, Calkins, Davenport,[2] Ewing, Flexner, Gies, Hiss, Lee, Levene, Levin, Lusk, Mandel, Meltzer, Park, Richards, Salant, Wadsworth, Wallace, Yaku.

Members Elected.—J. G. Adami, R. A. Hatcher, Yandell Henderson, G. N. Stewart, C. G. L. Wolf.

ABSTRACTS OF REPORTS OF ORIGINAL INVESTIGATIONS.[3]

The Accommodation of the Eye, with Demonstrations.—By professor Theodor Beer, of the Univer- of Vienna. Two principles are realized in the accommodation of an eye, that is constructed as a "camera obscura:" (1) Change of curvature of refracting surfaces, principally the lens; (2) Change of distance between refracting mediums and image screen, principally distance between lens and retine.

1 There is only *increase* of curvature, principally of the anterior surface of the lens, during active accommodation. We observe it in mammals, birds and reptiles (lizards, crocodiles, turtles, very few snakes). Experiments were made before the society to show the increase of curvature of the lens in the eye of the water turtle—proofs of Helmholz's theory of accommodation.

.2 Accommodation by change of the distance between lens and retina is possible in two directions: (*a*) In cephalopods and fishes, which are normally short-sighted—accommodation for objects at a distance is effected by a movement of the lens toward the retina. In the eye of the fish there is a muscle, *Musculus retractor lentis* Beer, which draws the lens toward the retina. (*b*) In *Amphibia* and most of the snakes, the lens is moved toward the cornea, away from the retina, by changes of the intra-ocular pressure.

Preliminary Communication on the Composition of the Liver After Subcutaneous Injections of Liver Extracts.—By P. A. Levene and L. B. Stookey. About two years ago the authors observed that it was possible to increase the resistance of rabbit blood against trypsin by treating the animal to subcutaneous injections of pancreatic extract. It seemed probable that the resistance of organs against other proteolytic enzymes than trypsin could be increased in an analogous manner. Rabbits were treated with saline liver extracts. The autolytic powers of the livers of such animals were compared with the autolytic powers of the livers of normal animals. It was found that the autolytic power of the organs was not diminished. It was also noted that the organs of the treated animals contained smaller proportions of nitrogen than the livers of the control animals and further, that the proportion of non-coagulable proteids, and that of non-basic nitrogen was higher than in controls. In order to accurately interpret the findings, the composition of the organs was compared. (See the appended table). It was noted that the amount of water and carbohydrates was not affected by the treatment, while the proportion of ethereal extract was higher in the organs of treated animals than in those of the control animals.

---

1 Proceedings reported by the Secretary, William J. Gies, Ph.D., of New York.
2 Non-resident.
3 The authors of the reports have furnished the abstracts. The secretary has made only a few abbreviations and minor alterations in them.

The Transformation of Negatively Heliotropic Animals (Gammarus pulex) into Positively Heliotropic Animals by Chemical Means.—By Jacques Loeb (presented by Simon Flexner). After it had been proved that the heliotropism of animals and plants is identical, it seemed desirable to find means by which positively heliotropic animals could be transformed into negatively heliotropic ones and *vice versa*. Groom and Loeb found that such transformation was possible in the nauplii of *Balanus perforatus* at Naples by the influence of light, inasmuch as these animals were positively heliotropic in very weak light and negatively heliotropic in strong light.[1] Later Loeb found that the marine copepods and young larvæ of *Polygordius* became positively heliotropic by the lowering of the temperature as well as by an increase in the concentration of the sea water, while they became negatively heliotropic under the opposite influences.[2] Moreover, Loeb observed that negatively heliotropic copepods can be made positively heliotropic by mechanical agitation,[3] and Miss Towle showed that the sign of heliotropism in *Cypridopsis* can be reversed through contact with solid bodies.[3] Holmes made the discovery that the positively heliotropic terrestrial amphypod, *e.g., Orchestia agilis* become negatively heliotropic when thrown into water.[4] of the fatty series; (2) many acids, except very weak ones, like boric acid; (3) certain salts, like ammonium salts.

Alkalies like NaOH, or Ba $(OH)_2$ and the neutral salts like NaCl or $CaCl_2$ bring about a scattering of the negatively heliotropic animals but do not make these animals instantly and without exception positively heliotropic, as do the anesthetics or the acids.

A few quantitative data may be mentioned here by way of illustration:

Ethyl acetate and similar esters instantly make all the *Gammarus* positively heliotropic in a concentration of about $^{m}/_{60}$. Ether requires a higher concentration, namely $^{m}/_{0}$. Ethyl alcohol brings about an equally rapid transformation of the negative heliotropic animals into positively heliotropic in a much higher concentration, namely $^{6}/_{2}$m. solution. Paraldehyd requires a concentration of about $^{m}/_{10}$. As far as the acids are concerned hydrochloric, oxalic and acetic acids make the animals instantly and without exception positively heliotropic in the concentration of about $^{m}/_{500}$. In boric acid the animals remain negative even at as high a concentration as $^{m}/_{10}$. NH_4Cl instantly makes the negatively heliotropic *Gammarus* positively heliotropic in a concentration of $^{m}/_{25}$. NH_4OH acts similarly in the

The author had tried in vain to change the sense of heliotropism in animals by chemical means, and this gap was felt the more keenly, inasmuch as he was led to believe that chemical changes might ultimately determine changes in the sense of heliotropism. Recently, however, the author succeeded in finding an instance where specific chemical substances are capable of transforming the sense of heliotropism in animals. The experiments were made with a fresh water gammarus (*Gammarus pulex*) which can be obtained at any time in large quantities at Berkeley. If one puts a large number of these animals suddenly into distilled water or into common tap water, they all become at first very negatively heliotropic. It is possible that this is caused by the mechanical agitation, connected with the transferring of the animals from one vessel to another, but this has not yet been ascertained with certainty. Half an hour or an hour later, the negative gathering of the animals becomes less dense, and the animals are scattered in the vessel.

These negatively heliotropic animals can be transformed instantly into positively heliotropic animals by the following substances: (1) Many of the anesthetics same concentration. As far as neutral salts are concerned they usually do not make the negatively heliotropic *Gammarus* positively heliotropic until the concentration is over $^{m}/_{4}$ or $^{m}/_{2}$ and even then, as a rule, no instantaneous and complete gathering of the animals at the positive side of the vessel can be produced, but only a slow and partial gathering.

As the concentration at which the transformation of negatively heliotropic *Gammarus* into a positively heliotropic animal is produced differs for different substances, and inasmuch as this transformation is brought about most promptly by such substances as diffuse most rapidly into the tissues, we must conclude that we are not dealing here with an osmotic but with a chemical effect

Trypanosomes and Bird Malaria.—By F. G. Novy and W. J. MacNeal. (Presented by Gary N. Calkins). The studies made before upon the malarial parasites of birds have shown the existence of four species or types. These are: *Proteosoma, Halteridium, Hæmamœba majoris*, Lav., *Hæmamœba Ziemanni*, Lav. In the course of an extended study of the parasites of birds, the authors have met with several new species and, since the number is likely to be still further increased, it seems desirable to attempt a classification. This the authors have tried to do basing it largely upon the type of mul-

4 Holmes. Am. Journal of Physiology, vol. 5, p. 211, 1901.

tiplication and the habitat of the parasite. Two genera will be given; one, *Plasmodium*, characterized by formation of segmenting forms in the peripheral blood and invasion of the fully developed red blood cells. The injection of these parasites results in an infection. For the other germs we use the priority name of Kruse, *Hæmoproteus*. This is characterized by an entire absence of segmentation forms in the peripheral blood, and, with the exception of two species which form a transition as it were between the two genera, invasion of young erythroblasts is the rule. The injection of the blood having these parasites does not lead to infection.

With this division the species are arranged as follows: A. *Plasmodium*, including parasites of man, some of birds and very probably some of cold-blooded animals. (1) *Plasmodium relictum*, syn. *Hæmamœba relicta, Proteosoma*. (2) *Plasmodium Vaughani*, n. sp. B. *Hæmoproteus* including chiefly parasites of birds and probably offering transitional forms to the *Hæmogregarines* of cold-blooded animals. (1) *Hæmoproteus Danilewskyi*, syn. *Halteridium*. (2) *Hæmoproteus Mac Callumi*, n. sp. (3) *Hæmoproteus Sacharovi*, n. sp. (4) *Hæmoproteus majoris*, Lav. (5) *Hæmoproteus Ziemanni*, Lav. (6) *Hæmoproteus Rouxii*, n. sp.

Plasmodium Vaughani, n. sp., is common in robins and resembles *Proteosoma* and may be easily mistaken for the latter. The hyaline body is smaller than that of *Proteosoma*, does not displace the nucleus, contains one large pigment granule and is readily recognizable by the presence of a large, bright, refractile, colorless globule. It segments and usually forms four cells. Canaries may be infected; apparently non-fatal.

Hæmoproteus MacCallumi, n. sp., found in mourning dove. Like *Halteridium*, which it resembles, it infects erythrocytes. Grows on one side and may completely surround the nucleus. The fully developed sexual forms fill and somewhat distend the blood cells. Microgamete formation observed. The infection cannot be transferred by blood injection.

Hæmoproteus Sacharovi, n. sp. This species, probably first observed by Sacharoff, who regarded it as a "leucocytozoon," is related to that of Danilewsky. Found in young mourning doves and elsewhere. Invasion begins with an infection of very young erythroblasts. As the parasite grows it pushes the nucleus to the periphery, where it is seen in the adult form on the outer edge as a cap, which is but a trifle larger than the nucleus of a red blood cell. The parasite is spherical, male and female forms common, latter predominate, blepharoplast distinct, adjoining or over the nucleus. Microgametes formation common. Infection not transferable by the blood.

Hæmoproteus majoris, Lav. This was found once by Laveran in a titmouse. This species is extremely common in robins and other birds. As with preceding invasion at early stage shows infection of very young erythroblasts, the small parasite lying next to the large round nucleus. As the parasite grows it pushes into the nucleus which becomes crescentric and may almost wholly surround the parasite. The adult sexual forms are large, about 10 to 12 microns in diameter, and are readily recognizable by the peripheral ring of the nucleus of the host cell. This cap may extend, and usually does, around two-thirds of the cell and even more. The blepharoplast is easily seen in female cells; microgamete formation common. No infection of other birds by injection of blood swarming with these forms.

Hæmotropeus Ziemanni, Lav., has been studied by Danilewsky, Ziemann, Laveran, Schaudinn and others. Forms long spindle-shaped bodies which are 30 to 50 microns in length. We have found this species or one closely related to it in the blood of a hawk. Sexual forms easily recognized.

Hæmoproteus Rouxii, n. sp., is very common in sparrows, and represents the very earliest possible infection of young erythroblasts, so much so that it is not feasible to exclude the possibility of their being leucocytes. As the parsite grows it pushes into the nucleus which assumes the form of a thick crescent. The parasite measures from 4 to 6 microns. Its plasma does not stain readily and sexual forms have not as yet been recognized. Apparently always associated with this cytozoon are minute crescentic free hemogregarines. These are but 4 microns long and are motile, crawling over the red blood cells in characteristic manner. Larger motile crescents, about 10 microns long, at times are present. Both large and small crescents are free and motile and, it is important to note, are present in the fresh blood at the moment when drawn. They cannot, therefore, be considered as oökinetes. They are hemogregarines and presumably constitute the extracellular stage of *H. Rouxii*.

It is to be noted that the last four mentioned forms all exert pressure in the nucleus of the erythroblasts, and, as a result, give rise to very peculiar types. They are all "leucocytozoa" of which, thus far, there has been but one type, that of *H. Ziemanni*. The view of Schaudinn that the latter is a trypanosome which ingests an entire erythroblast by attaching itself to such by one end becomes untenable, inasmuch as all stages of infection, from the earliest to the latest, can be readily observed in the case of *H. Sacharovi* and *H. majoris*. The authors regard the large spindle-shaped *H. Ziemanni* as an infection of an erythroblast and the elongated form as consequent upon an alteration of the wall of the host-cell leading to increased osmotic pressure which, acting on the poles, gives rise to the spindle-shaped forms.

In addition to the parasites mentioned, birds harbor very frequently *Filaria* and *Tryponosoma*. In the case of the *Filaria* while the peripheral blood may contain but a few, the heart blood may contain large numbers. Trypanosomatic infection of birds is far more common than has been supposed. The largest number of infected birds seen by any one observer was eight, which were found by Dutton and Told, in Senegambia. The reason why they have not been found more commonly is because they are present in very small numbers, usually not more than one or two flagellates in a drop of blood. By microscopical and cultural methods the authors have been able to detect trypanosomes in the blood of 33 birds. Of this number 18 were detected by direct blood examination (of the 18 birds, 10 were tested culturally and gave growths), and 15 by means of our cultivation method, that is to say, in 15 cases where the microscope failed to show trypanosomes, the culture method showed them to be present. This shows that, as in the case of the bacteria, the cultural method is a more delicate means of detection of small numbers of parasites than is the microscope. The occurrence of these trypanosomes, with reference to the cytozoa mentioned, is of special interest. Thus, 13 out of the 33 trypanosomes were unaccompanied by any intracellular parasites, while 20 were associated with one or more kinds of cytozoa. It was not an uncommon thing to find multiple infection, that is, the same blood harboring at one time, in addition to trypanosomes, two or three different species of intracellular parasites.

Again, in addition to the fact that trypanosomes may be present without any other parasite, the interesting fact that when thus associated there is no constant rela-

tion between the two. In other words, the same trypanosome may be found at one time with a *Protcosoma*, at another time with a *Halteridium*, or with *H. Sacharovi* or with *H. majoris*, etc.

In 25 out of the 33 cases mentioned cultures were obtained. Nearly all of these have been carried through a series of subcultures or new generations. Here another important fact was brought out. The cultural method is not only the best means of detecting trypanosomes in the blood, but it is the best means of differentiating them into species. A study of 25 cultures attained shows that they represent three, if not four and possibly more distinct species. The cultural characteristics are extremely well marked and offer an admirable means of differentiation. [The detailed account of these forms must be left to the full paper by the authors on this subject.]

One species, however, more common than any of the others must be considered at this point. Its cultures present an extremely interesting appearance and are unusually luxuriant. They show two types of cells. One of these is round or in short spindles which always occur in rosettes with the flagella directed centrally as in the case of *Trypanosoma Lewisi*. The other type is long and very slender, almost a mere line, and is extremely motile, traveling forward and backward with great rapidity. Very often two cells unite by their posterior ends; at times agglutinations are found and in these the whips are found situated on the outside of the mass. This long, slender, type corresponds exactly to the "*Spirochæte*," described by Schaudinn, while the other type agrees with his "*Trypanosoma*."

It is noteworthy that inoculation of the trypanosome cultures, even in large amounts into birds, failed to produce any cytozoa. In one case a canary infected with such a culture showed trypanosomes in its blood for three months without any sign of an intracellular parasite. These facts are of importance because of their bearing on the recent views of Schaudinn, regarding the relation of trypanosomes to the intracellular parasites. As is well known this distinguished protozoölogist believes that in the case of *Halteridium* the sexual forms unite in the stomach of the mosquito to form oökinetes which then develop into indifferent male and female trypanosomes. This type agglutinates with the flagella directed toward the center. In the case of the *H. Ziemanni* he holds that a similar change occurs in the mosquito, giving rise to long slender spirochætes, which agglutinate with the flagella directed outward. The injection of suspensions of such infected mosquitoes produced the characteristic infection with the hemocytoza.

It will be seen that the results obtained by the authors do not bear out Schaudinn's conclusion. The authors have shown that birds may harbor trypanosomes even for months without showing any intracellular parasites. On the other hand, birds rich in such cytozoa may contain no trypanosomes. Thus, cultures attempted from 26 of such heavily infected birds failed to show any growth. Again the presence of trypanosomes is not associated with any one form of intracellular parasite. Furthermore, the cultural method shows the existence of several distinct species of trypanosomes, and among these is one which presents at the same time both types described by Schaudinn as stages on the one hand for *Halteridium*, and on the other hand for the *Leucocytozoon* of Danilewsky.

The authors, therefore, conclude that trypanosomes in birds may be met with as several distinct species wholly unrelated to the intracellular parasites. The greatly diverging conclusions reached by Schaudinn and the authors must be ascribed to the fact that Schaudinn worked with "*mixed cultures*," as developed in the body of the mosquito, whereas the authors have employed strictly pure cultures of these flagellates.

[The authors hope to publish the full detail of this investigation in the January number of the *Journal of Infectious Diseases*.]

The Gradual Decrease in Bacteria of the Production of Agglutinable Substance.—By William H. Park. At the last meeting of the Society of American Pathologists and Bacteriologists, an informal statement of this fact was made by Dr. Welch, for Drs. Marshall and Knox. The experiments of Dr. Collins and the author are recorded because they were undertaken in a slightly different way and also because a certain number of confirmatory observations are of value. The maltose fermenting paradysentery bacillus of Flexner was grown for twenty-four hours on each of eleven consecutive days in fresh bouillon solutions of the serum from a horse immunized through oft-repeated injections of the bacillus. The serum strength in the solutions used was one and one-half, four and fifteen per cent. The serum agglutinated the culture before its growth in the solutions in dilutions up to 1:800, and was strongly bactericidal in animals. After eleven transfers the culture grown in the fifteen per cent. solution ceased to be distinctly agglutinated by the serum in any dilution, and ceased to absorb from the serum any appreciable amount of the agglutinins acting upon the original culture. The cultures grown in the one and one-half and four per cent. solutions were changed to a less degree and agglutinated in dilutions up to 1:100 and 1:60 respectively, and continued to absorb agglutinins. The recovery of the capacity to be agglutinated was very slow in the culture grown in the strongest serum solution, when it was from time to time transplanted on fresh nutrient agar. The other cultures recovered this characteristic more rapidly.

The first culture, after growth for sixteen weeks, during which it was transplanted 43 times, agglutinated in dilutions up to 1:200 and, after twenty weeks, in dilutions up to 1:400. The culture grown in four per cent. solution of serum agglutinated after sixteen weeks in dilutions up to 1:500, and the one and one-half per cent. agglutinated in dilutions up to 1:800. This diminution, and final, almost complete, lack of development of agglutinable substance in bacteria grown in a serum rich in agglutinin and immune bodies is interesting, both as showing a rapid variation in bacteria of essential characteristics, and as posibly indicating one means of adapting themselves to resist destruction in the living body, since the bacteria which ceased to produce agglutinable substance and probably, also less substance with affinity for other antibodies, might be considered less vulnerable to these substances.

It is not certain that the agglutinin in the serum causes the change in the bacteria, for solutions may agglutinate and still not produce this effect. The fact has been noted that the horse serum of animals not immunized has much the same effect on the cultures as the immune serum. Although this suggests that the change is not due to antibodies, it does not prove this, since the serum of a horse before injections is rich in antibodies, for the typhoid and colon groups, due possibly to the passage of bacteria from the intestines into the circulation.

The author's explanation of the process is that there are substances in the serum which attack certain parts of the bacteria, such as the agglutinable substance. In the increase of bacteria in the serum those which produce the least of these substances are least inhibited and

therefore develop most rapidly. When cultures are made from serum solution to serum solution daily, a gradual differentiation takes place until finally bacilli producing almost no agglutinable substance develop.

Some Mendelian Results in Animal Breeding.—By C. B. Davenport. The essence of Mendelism in inheritance is its alternative character. In this it is opposed to blending inheritance (as in human skin color) which had been regarded as the typical sort of inheritance. At the station for experimental evolution of the Carnegie Institution, certain new cases of non-blending inheritance have already been found. Among sheep it appears from Dr. Alexander Graham Bell's records, that the offspring of two black sheep are (probably always) black, although one or more of the grandparents were white. It looks as if black color (like albinism) might be recessive. Among canary birds it is found that of the offspring of crester and of plain-headed birds, some are crester and some are not. Poultry have been studied because of the numerous characters they exhibit. When a Japanese long-tailed, clean-legged cock was crossed on a white bantam hen, the two surviving offsprings were highly colored, like the father, and had abundant feathers on the legs like the mother. The crested characteristic of poultry is peculiar, being sometimes dominant and sometimes (apparently) blending with the combed condition when the cross is made.

On the Decomposition Products of Epinephrin.—By John J. Abel and R. de M. Tavean. (Presented by William J. Gies.) The empirical formula, $C_{16}H_{13}NO_3.\frac{1}{2}H_2O$, adopted by Abel for that member of the epinephrin series, which he has called epinephrin hydrate (the adrenalin of Takamine) is at present, the subject of an acute controversy. The authors are now engaged in a repetition of the analytical work on which Abel based the above formula for epinephrin hydrate. In view of the suggestion of Abderhalden and Bergell that this substance should be prepared in a way that avoids oxidation by the air, the authors have undertaken the laborious task of preparing and purifying it in an atmosphere of hydrogen.

The authors wish to remark here that the $\frac{1}{2}H_2O$ of their empirical formula has always been regarded by them to be water of constitution, and not water of crystallization, as their opponents have taken for granted. The assumption that this $\frac{1}{2}H_2O$, so easily removable by high heat and by various acids, is water of constitution necessitates doubling the present empirical formula, a procedure which is at variance with the molecular weight determinations of v. Fürth and Jowett. These determinations are, however, open to serious objections as will be shown at length elsewhere. Work on the decomposition products of both alkaloidal epinephrin and epinephrin hydrate has been continued. The basic substance, $C_8H_4N_2O$, which is obtainable equally from both forms of epinephrin, has been decomposed by treatment with caustic potash into ammonia, (NH_3) methylamine ($CH_3.NH_2$) and methylhydrazine ($HC_3.NH.NH_2$) of these decomposition products methylamine is also obtained from both modifications of epinephrin. Methylhydrazine has thus far not been obtained either from epinephrin or its hydrate. This degradation product is of great importance in throwing light on the chemical constitution of the new base, $C_8H_4N_2O$,as its appearance, under the circumstances described, proves that the two nitrogen atoms of this base are directly combined one with the other, and suggests among other things for this base a ring structure such as is found in bodies of the pyrazolon $\left(\begin{matrix} N\text{———}NH \\ \| \quad\quad | \\ CH{=}CH_2\text{—}CO \end{matrix}\right)$ series. It may here be noted that pyrazolin carboxylic acids can easily be made to yield hydrazine.

A full discussion of the bearing of the above results on the constitution of epinephrin must be deferred until it has been determined whether the oxidation product, $C_8H_4N_2O$, is of a primary or of a secondary character. In any case an adequate constitutional formula for epinephrin must be able to account for all the decomposition products that have been named. In conclusion it may be mentioned that the authors have repeatedly obtained, in their recent work, small quantities of skatol $\left(C_6H_4{<}\begin{matrix} C(CH_3) \\ NH \end{matrix}{>}CH\right)$ on fusing epinephrin hydrate with caustic alkalis—a product which has been erroneously supposed to be obtainable only from the monobenzoyl series of epinephrin compounds.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held November 7, 1904.

Cirrhosis of the Liver.—The condition was briefly discussed by Dr. Osler preliminary to a report of a case representing one of the rare forms. The subject was, he said, much confused in the literature, particularly in France, where a multiplicity of forms had been described, and a most complex classification constructed. Between these text-book forms and the actual clinical findings there was not always agreement, and the result has been a good deal of confusion, particularly on the part of students. Cirrhosis was best considered as divided into three types: The portal type, in which the involvement is chiefly in the peri- and sublobular veins—the biliary type, and the capsular type—the capsule being involved alone or as part of a general peritonitis.

Biliary Cirrhosis of Family Type.—There was not, Dr. Osler said, general agreement as to the existence of a definite biliary type of cirrhosis, the English particularly denying it. He expressed his own belief, however, in such a clinical entity exhibiting the following characteristic features: A protracted course (after five to twelve years), a persistent, chronic, intense jaundice; pains, often marked, in the hepatic region; tendency to occur in the young (sometimes in children) as distinct from alcoholic cirrhosis; absence of signs of portal obstructions (ascites, hemorrhoids, etc.); frequency of hemorrhages (mucous and cutaneous); a large, smooth liver found on examination. Other causes of this form of enlargement of the liver should, however, be always kept in mind, for hypertrophy of this type is seen in the alcoholic liver, in the fatty liver and in cases of regeneration after atrophic cirrhosis.

Report of a Case of Hanot's Cirrhosis.—The case reported was of a young man of twenty-three years, with good family and personal history, and without alcoholic or luetic taint. At five years of age he had had an attack of jaundice, from which he recovered. Five years before admission the persisting jaundice had first appeared, and it had been constantly present ever since. With it there had been itching and epistaxis, but no pains, anemia or fever. The liver was below the costal margin, the spleen was not felt, and there was no leucocytosis. Under the administration of calcium the blood coagulation-line was reduced to about two minutes, and an exploratory operation was done. No obstruction was found in the bile passages. The patient died in a few days of hemorrhages. It was found later that the condition was familiar, two of

the patient's brothers and one sister suffering from persistent jaundice. Dr. Osler, in connection with this case, reviewed the clinical features of two other patients treated some years ago in the Johns Hopkins Hospital for the same condition. These were two brothers, aged thirty-two and thirty-four years, with a healthy family and no alcoholic history. Both had been jaundiced several years, and suffered from recurring hepatic pains with hemorrhages from nose and gums. The liver was enlarged in both cases. One of the patients died with signs of a terminal infection, and staphylococci and streptococci were found in the blood.

Pathological Specimens of Biliary Cirrhosis.—Dr. MacCallum showed the specimens and described the pathological changes found at autopsy in the first case reported by Dr. Osler. The gall-ducts were apparently normal. The liver was dark-green and soft, and there were, macroscopically, no fibrous strands seen in it. It showed no signs of gross stagnation of bile. Microscopically there were seen in the central portions of the lobules disintegration, phagocytosis of bile, infiltration with leucocytes, but no inflammation of the ducts. The cause of the jaundice in these cases was discussed and Eppinger's theory of a biliary thrombosis with rupture of the bile capillaries and extravasation of bile into the blood was said to be the most likely one. Dr. Osler referred to the presence of bile in the stools of these patients in spite of the intense jaundice which might be more marked than in any condition except malignant disease.

Crossed Dissociated Sensory Paralysis.—Dr. Thomas exhibited a case showing this dissociated paralysis with a lesion in the medulla. The patient was a man, aged forty-eight years, of good family and personal history, who, from September, 1904, on had been suffering with attacks of vertigo every ten or twelve days. The attacks lasted fifteen to twenty minutes, and were accompanied by pain in the left side of nose and face, numbness in the side and a sense of "everything going round." Between attacks he was well. On October 2 he had an attack similar to the others, but more severe; and from this he never recovered. His voice became hoarse, a disagreeable feeling became almost constant in the left side of the face, there was numbness of the left side and continuous vertigo. On occasions there was perspiring of the right side of the face. There was no nystagmus. The seventh and eighth cranial nerves were normal, and there was no change in the mouth. Throughout the distribution of the fifth cranial nerve on the left side there were analyesia and thermanesthesia. The pharyngeal reflex was absent, there was paralysis of the left side of the larynx, the palate fell slightly to the left, and the tongue was protruded slightly to the right. Sensory changes in the right arm were the same as those on the left side of the face. The muscular strength was good, but the left hand and leg were unsteady. The deep reflexes were normal on both sides. On the right side the abdominal reflex was active; on the left it was absent. There was unilateral ataxia of the left foot. The patient had been in the hospital two weeks, and was much improved. The diagnosis was of a lesion in the medulla with disturbance of the sensory fibers passing to the cerebellum in the region of the restiform body. The lesion must have been above the decussation of the fibers of the fifth nerve, and below the decussation of the sensory nerves of the body. These data, together with the involvement of the tenth nerve and the escape of the seventh and twelfth located the lesion exactly. The important features of a similar case in the Johns Hopkins Hospital some years ago, were described by Dr. Thomas. This patient presented a symptom-complex much like, though not identical with, the one reported. He died suddenly, and at autopsy there was found a thrombus of the right vertebral with the posterior, inferior, cerebellar artery. Several similar cases have been described in the literature. In Wallenberg's patient (reported in *Deutsche Zeitschrift für Nervenheilkunde*) diagnosis of thrombosis of posterior-inferior cerebellar artery was made during life, and this condition was found at autopsy. In Monakow's case, however, the same diagnosis was made from a similar symptom-complex; but at autopsy an aneurism of the vertebral artery was found causing pressure destruction of the cerebellum. The prognosis in such conditions is good, for partial recovery, but certain features usually persist.

Situs Transversus and Atresia of the Pylorus.—This condition was briefly reviewed by Dr. Little in connection with a case reported. The monster had been born of a mother aged thirty-three years, who had been admitted to the hospital during the seventh month of her pregnancy. The child when born weighed 2,350 grams. Hydramnios complicated the delivery. The child's head was about normal, but it had the typical "old-man" appearance. Shortly after birth it vomited 1½ pints of amniotic fluid, and the following day passed some meconium. Feeding was attempted with modified milk, but vomiting occurred approximately after every second feeding. On the fifth day mother's milk was given, and subsequent gastric lavage showed that the food had not passed out of the stomach. There was bile in the stools. Operation was decided on, and a posterior gastro-enterostomy done. The patient died next morning. At autopsy complete situs transversus was found, the right lung had but one lobe, there was no connection at all between stomach and duodenum, and the latter began in a pouch containing the ampulla of Vater. The etiology of this condition (atresia of the pylorus) is not clear. Error in development, volvulus, and local fetal, luetic peritonitis have been suggested as the cause. Ahlfeld thought it was due to the persistence of the omphalomesenteric duct, while Küttner believed in an arteritis and thrombosis of the intestinal arteries as the origin of the deformity. A congenital malformation of the vessels was found in this case—the gastric and splenic arteries anastomosing and short-circuiting the pancreatico-duodenal branches of the hepatic.

MEDICAL AND CHIRURGICAL SOCIETY OF MARYLAND.

Stated Meeting, held November 4, 1904.

Section on Clinical Medicine and Surgery.

A Case of Traumatic Asphyxia.—Dr. Randolph Winslow reported a case of traumatic asphyxia. This condition was recently reviewed by Beach and Cobb in the Annals of Surgery, and at that time only seven cases (including that of the author's) had been reported. The accident always results from the application of a compressing force, kept up for some time and sufficient to prevent breathing. The essential feature is the remarkable blue discoloration of face and neck. In some cases the extremities have been

involved. The patient reported was a man, aged twenty-two years, who had been caught between the top of an elevator and the roof of the shaft. He had been kept in this position by the ascending elevator for some moments, the force, which doubled his body up like a jack-knife, being sufficient to produce a laceration around the rectum from the heel of the shoe. The patient did not lose consciousness, but suffered great agony, and felt "as if he would burst." His pulse, when he was first seen, was 120, respiration 40, temperature normal. There was bloody expectoration and epistaxis; and the fourth, fifth and sixth ribs on the left side were fractured. Subcutaneous emphysema was present; but there was no blood in the urine, which had to be drawn with a catheter. The pupils were equal, and reacted to light, there was conjunctival ecchymosis. Sight and hearing were good. The most remarkable feature in the examination was the discoloration. The head, face and neck to the level of the collar were dark blue, the charge being a punctiform one, like the scarlatina rash. Pressure caused no disappearance of the "cyanosis." The patient was shocked, and was practically untreated, except for absolute rest and the usual attention to his other injuries. On the day after admission his temperature rose to 100.8° F., but with this exception, convalescence was uneventful. He was out of bed on the eighth day, and four days later left the hospital, though the discoloration had not then entirely left.

Pathology of the Condition.—Dr. Winslow said that this condition was not infrequently seen in patients dead from compression, but it was extremely rare in the living. Previous to the work of Beach and Cobb it had been thought to be a cutaneous hemorrhage; but these authors showed, by histological examination, that no extravasation occurred, the essential charge being a dilation of the capillaries. This observation was confirmed by Dr. Winslow. A piece of excised skin having been examined after hardening in Zenker's fluid and staining with hemotoxolyn and eosin and with Van Gieson's stain. Distention of the capillaries, absence of extravasation of blood and a practically normal skin were found.

The Treatment of the Stump of the Appendix.—This subject was discussed by Dr. H. A. Kelly. The development of appendicitis in the history of surgery had, he said, been associated with the operative treatment of appendicitis. Nowhere else in surgery was more clearly shown how much may be accomplished in a small field by careful work. The development of the operation was as good an example as could be had of the evolution of operative technic, several workers each adding a small improvement until the procedure had become satisfactory to all. After the recognition of appendicitis as a clinical entity seventy-five years had occurred before it was intelligently treated by the surgeon. There were two reasons for this. One was the invention of the name "typhlitis," which had resulted in a false idea of the pathology of the condition, and the other was the authority of Dupuytren, who opposed advance in this direction. Clear light first began to dawn when Reginald Fitz published his classical paper; and the subject was soon cleared up by the work of Morton, Sands, Parker, McBurney, Bull, Weir, Deaver and Senn. Krönlein in 1844 was the first to remove an appendix. He opened a pericecal abscess, ligated and amputated the appendix, and closed without drainage. The patient died. Hall, at the Roosevelt Hospital in 1886, ligated and amputated an appendix and drained the abdomen successfully; but Morton in 1887 was the first to operate on a case of appendicitis, in which a definite diagnosis had been previously made. Ligation and amputation with evisceration of the abscess and drainage resulted in recovery. In 1889 Treves first sutured the peritoneum, and Senn, in the same year, first covered the stump with peritoneum. The cuff operation was first described by Fowler, and Dawbarn was the first to advise stretching of the lumen and invagination of the organ into the cecum. Other methods which had been described were: Edebohls's (invagination of the whole appendix which is left to slough into the cecum), Deaver's (amputation in the cecum), and the method of Halsted and Finney (application of three clamps, withdrawal of middle clamp and amputation at that point). The danger in any method was said to be that of contamination of the surrounding peritoneum, and if this risk could be eliminated an ideal procedure would result. Donnes's electrothermic cautery would accomplish this purpose, but the great objection to its use was the necessity for expensive and elaborate electrical apparatus.

Exhibition of a New Instrument for Dealing with the Appendix Stump.—A new instrument was shown and its application in the treatment of the stump of the appendix demonstrated by operations on pathological material. The base of the appendix was caught between the blades of a powerful crushing forceps, which were provided with beveled edges so arranged that the point of an actual cautery could rest on them and convert them into cooking irons. The appendix was then amputated by the cautery, and its stump thoroughly cauterized. The blades of the crushing forceps were then heated slowly by the cautery, the tissues which had been crushed between them being in this way thoroughly cooked and sterilized. When the forceps was removed a thin, transparent, flat area was seen representing the stump of the appendix, which had been thoroughly crushed, completely sterilized and absolutely sealed. A seroserous suture was then placed in the ordinary way.

NORTH BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held October 8, 1904.

The President, Samuel Wolfe, M.D., in the Chair.

SYMPOSIUM ON CHRONIC BRIGHT'S DISEASE.

The Etiology and Diagnosis.—This part of the subject was discussed by Dr. Samuel Wolfe, who stated that one usually has as an underlying cause, either inflammation or degeneration, probably both, and that it was a mooted question as to whether there was ever degeneration without inflammation. He referred to the fact that in many cases back of the inflammation and degeneration there was a toxin or specific infection, and cited among the causative factors, malaria, tuberculosis, amyloid degeneration, syphilis, exposure, excessive use of alcohol, particularly beer. The disease is more frequent in males than in females and generally occurs in early life, before the fortieth year. He confined his remarks to the chronic parenchymatous variety, and stated that the condition occasionally was associated with a slight form of pyemia, especially after pregnancy, or with anemia. The urine is scanty with a specific

gravity normal or slightly higher; a low specific gravity being indicative of the interstitial variety. The histological elements are more scanty in the chronic interstitial variety, and the edema is more marked. He referred to the diagnostic value of accentuation of the aortic sound, which, while not indicative of any specific form of Bright's disease, was very suggestive of renal trouble. Careful chemical and microscopical study of the urine; the condition of the heart; and the slowly progressive blood deterioration must remain the cardinal points in the diagnosis.

Prognosis and Treatment of Chronic Nephritis.—This was read by Dr. A. C. Morgan, in which he stated that, as it was impossible to repair the damage done to the kidney, the treatment must necessarily be of an inhibitory character. The prognosis, he stated, was difficult to determine owing to the uncertain time the disease has existed, and the complications which may arise, the younger the patient the more serious is the prognosis, the variety in such cases being usually the parenchymatous. He referred to the fact that death was not always caused by the disease alone, and cited as chief among the terminal complications, pneumonias, particularly bronchopneumonia, grippe, cerebral hemorrhage, cardiac dilatation, and inflammation of the serous membranes, pericarditis being the gravest of the latter condition. In uremia, accompanied by convulsions, he stated, the prognosis was grave. In the treatment, especial attention should be directed to the removal of the cause, and much can be accomplished by the treatment of the patient as well as the disease. Careful attention should be given to the general condition and hygiene, flannels should be worn the year round, in order to stimulate the activity of the skin, and, if possible, the winter passed in a warm, equable climate. Mental labor must be cut down and exposure avoided. Cold bathing should be avoided, and benefit is derived from massage, rest in bed for ten hours out of twenty-four, or the entire time when the paroxysms are severe; malt liquors and spirits should be avoided and carbonated waters used freely. Nitrogenous foods should be reduced and milk may form an important part in the dietary. The treatment should be directed to arresting the sclerotic or degenerative changes and overcoming the anemia, for the former of which may be used potassium iodide, hydriodic acid and mercuric chloride and for the latter, arsenic and iron. He then discussed, in detail, the treatment of high tension, low tension, effusions, drowsiness, dropsy, asthma, edema of the glottis, epistaxis, obstinate vomiting and diarrhea, pruritis, palpitation, and uremia, for the latter condition venesection being recommended. Chloroform, chloral and the bromides, and in the parenchymatous variety morphine in good doses may be used, but in the interstitial form should be used but sparingly, although the author cited a case in which for five years he had employed morphine hypodermically for the asthma which had resisted all other measures, followed by pilocarpine the morning following without any untoward results.

Dr. James Tyson, in the discussion, said that while it had been stated that the pathology of chronic nephritis was so indefinite that no treatment could be based on it, he felt that this was going too far. He stated that there was no known agent by which the restoration of the structure of the kidney could be accomplished, and that the treatment naturally divided itself into two parts: (1) The placing of the patient in a condition which is most favorable for nature to assert herself and favor change in the structure, if possible, and (2) the treatment of the symptoms. He referred to the former method of the enormous use of drugs to diminish the albuminuria, and stated that there was no remedy which would prevent the transudation of albumin when conditions favor it. He recommended rest in bed for a few hours in the middle of the day in the mild cases, and longer if the case was severe. He believed that the distinctions between white and red meats were unfounded, and recommended that, instead of prohibiting red meats, the moderate use of all meats and, except in the acute exacerbations, a moderate quantity may be allowed. Climatic treatment is of value and the winters, is possible, should be passed in a warm climate. The treatment of the symptoms should be directed to the diminution of arterial tension. In the severer forms, rest in bed is absolutely necessary; massage is also of value. He felt that the general practitioners frequently made a mistake in advising the too free use of water. Puncture under aseptic precautions was recommended in dropsical cases, and the danger from sepsis was expressed as practically nil. Venesection and intravenous injections of normal salt solution was recommended in cases of uremia. In regard to the iodide of potassium, he stated that if it can be used without producing unpleasant symptoms, it may be of value, but the bichloride of mercury he did not look upon as of any use.

Dr. Wendell Reber stated, that the ophthalmological changes were of two kinds, degenerative and hemorrhagic; the inflammatory changes being most likely to occur in the acute forms, while in the chronic conditions, there are more likely to be degenerative changes. He referred to the work of Dodd, who some years ago collected 700 or 800 cases and submitted statistics showing the value of these observations in computing the probable duration of life. He referred to the observation of a number of cases made by himself at Blockley, and stated that while about 45 per cent. showed albuminuria, but very few revealed eye-ground changes, and this had been further confirmed by the observations he had made at the Polyclinic Hospital. He reported the case of a male, thirty-two years of age, who had had albuminuria for at least twelve years, although he has been giving careful attention to hygiene and his habits are almost ideal. At one time he was able to find a few fine yellow spots, but they disappeared and have not recurred. He also referred to another case which had been watched closely for a long time, and in which there were no changes observed until shortly before death, when violent degenerative changes occurred.

Dr. William H. Good referred to the fact that according to physiological chemistry, the osmotic pressure of fluids depended not so much upon the kind of molecules present, but upon their number, and felt that perhaps the same line of reasoning would explain the effect of large quantities of proteids, by increasing the osmotic pressure of the blood, which must be gotten rid of through the kidneys, and also discussed the question as to whether this action was due to a chemical substance or to the back of some internal chemical secretion.

Dr. W. Hershey Thomas referred to the various surgical procedures, which had been resorted to for the relief of this condition, and stated that, here as elsewhere, much more valuable information could be learned regarding the pathology of the condition during operation than after death. After which he referred to the operations by Edebohls, Harrison, Israel, Guiteras, Van Cott and others, giving in detail the different operations performed by operators and the results.

BOOK REVIEWS.

CHINESE MADE EASY. By WALTER BROOKS BROUNER and FUNG YUET MOW. The Macmillan Company, New York.

"AS HARD AS CHINESE" has almost passed into a proverb, therefore it is with something like a gasp of astonishment that we first catch a glimpse of the title of "Chinese Made Easy." Yet here it is, a rather bulky volume to be sure, but cheerfully bound in red and gold, so alluring in appearance that one feels eager to open the gay covers at once. Following true Chinese order the reader must turn to what would be the last page of an American book, and here he encounters an *Introduction* by Dr. Herbert A. Giles, of the University of Cambridge, a scholar of no small repute, who is himself the author of several works on the study of Chinese. Thereafter follows the *Preface* where the authors, Dr. Walter Brooks Brouner, of Columbia University, and Fung Yuet Mow, a Chinese city missionary in New York, briefly set forth the motives which inspired them to present this work to the public, and point out the advanages of their method of presentation over those usually employed in teaching Chinese to foreigners.

The greatest innovation is the abandoning of the usual system of "tones" or "breathings," that is, the placing of circumflex accents at the corners of certain Chinese characters, in the effort to distinguish the same character as applied to different things. This method, the authors claim, is artificial, unnecesary and never used by the Chinese themselves, as they are able to distinguish the same character used in different contexts, exactly as we recognize the difference between the English words *pane* and *pain*, identical in sound, but varied in meaning. This "tone" system has always been a great obstacle in the path of all European and American students of Chinese, and its removal does much to make the language appear much more "easy" than has ever before been the case.

The authors also lay stress upon the fact that Chinese, although originally a monosyllabic tongue, now consists largely of compound words, and these compounds may be readily analyzed into their original component parts. Chinese has no alphabet, as has been frequently noted, but it does possess 214 radicals or "root words," from which all the characters used in the written language are made up. The book sets forth a rational method of analyzing and understanding the very numerous characters used in writing Chinese, and supplies a vocabulary of words ordinarily employed in writing and speaking, together with instructions for using a Chinese dictionary. These are only a few of its many features of interest, but will serve to point out the entirely new path which the authors have opened up to the student. The book deals with only one of the main dialects of China—that is, the Cantonese. This particular dialect was selected on account of the fact that the greater part of the Chinese now resident in this country are natives of the Canton provinces. The written language is the same all over the Empire.

"Chinese Made Easy" bears throughout the evidence of the most detailed and painstaking labor, and is certainly a very noteworthy addition to the existing text-books of that obscure and formidable language. Yet, while we join with the authors in the hope that a day may come "when a knowledge of the Chinese language will be as common an accomplishment as a knowledge of German, French, Spanish or Italian is to-day," we cannot help fearing that that day is still some time in advance. But to those who have an urgent desire to add a knowledge of Chinese to the list of their linguistic accomplishments, "Chinese Made Easy" may be most heartily recommended as offering by far the most simple, practical and "common-sense" method of acquiring this language which has yet been presented to the American student.

LIGHT ENERGY. Its Physics, Physiological Action and Therapeutic Applications. By MARGARET A. CLEAVES, M.D. Rebman Company, New York.

SO MUCH has been heard of the action of light in medicine in recent years that a book like the present, which contains all the scientific principles of light action, will fill a definite want. The book is excellent in make-up, in matter and in the form in which it has been cast. The first 130 pages contain the Physics of Light, then 300 pages are devoted to the biological effects of light in its various available forms. Light exclusion and its beneficial effects in pathological conditions take up two chapters, some 40 pages. Various forms of radiation, including the N-rays radium and fluorescence are treated, and, finally, the pathological effects of light. In readily available form the book contains all the physician may desire to know about the use of light in medicine. In its thoroughness the work reminds us more of some of the foreign monographs than what is usual in this country. We are glad to welcome it as an addition to American medical literature.

SURGICAL TREATMENT OF BRIGHT'S DISEASE. By GEORGE M. EDEBOHLS. Frank F. Lisiecki, New York.

IT is certainly gratifying to have from the pen of the surgeon, who has done most in America to popularize the surgical treatment of chronic nephritis, a concise and lengthy monogram on the subject. Two-fifths of this book, which comprises over 300 pages, are devoted to the author's contributions to renal decortication, which are arranged in chronological order of publication. The remaining three-fifths are entirely new matter, never before published. This deals almost entirely with the results. Not an insignificant number of pages of this interesting volume are consumed in discussing the question of priority.

The histories of seventy-two cases are given in full and are followed by a very careful analysis. It is almost needless to state that the author's conclusions are to the effect that decapsulation is essentially the method of treating chronic nephritis. Whatever may be the opinion of the surgical profession at large, the advent of this book must be looked upon as a justification of the author's well-known views upon the subject. One closes it with the conviction that whether or not the author's interpretation of the manner in which he obtains these results, is correct or incorrect, the improvement noted in so many cases, whatever its source, justifies, under favorable conditions, the employment of surgical treatment for chonic nephritis.

BEAUTY THROUGH HYGIENE. Common Sense Ways to Health for Girls. By EMMA E. WALKER, M.D. A. S. Barnes & Company, New York.

THE series of which this little work is one includes a number of books of great practical interest to the modern woman, but none, we venture to say, that is written with more practical directness, with less waste of words, or with more careful attention to what is absolutely necessary for an easy understanding of the matter in hand than the present volume. All the details of the relations of health and beauty are simply

but thoroughly treated. The necessity for consulting a physician rather than take drugs by friendly or advertisers' suggestions is pointed out, yet if the book has a fault, it is that perhaps there are more drug hints in it than is quite suitable for the general public, especially as it is likely to be used mainly by young people.

Epitome of Nervous and Mental Diseases. By Joseph Darwin Nagel, M.D. Lea Brothers & Company, Philadelphia and New York.

Nervous and Mental Diseases are apt to be the bête noir of the medical student and the young general practitioner of medicine. If approached with confidence and systematic method they prove interestingly problematic instead of hopelessly complex. This little volume contains just the information likely to start the seeker on the road to a definite knowledge of one of the most important subjects in modern medicine. In spite of its small size it is quite complete and satisfactory in detail and contains some helpful illustrations.

The Principles of Hygiene. By D. H. Bergey, A.M., M.D., Assistant Professor of Bacteriology, University of Pensylvania. Second Edition. W. B. Saunders & Company, New York, Philadelphia, London.

Dr. Bergey's book, in its second edition, contains some excellent additions. Now that animal parasites have become so prominent a feature even of life in the United States, the chapters on these pests and especially the suggestions as to prophylaxis, are sure to be valuable. The paragraphs on fleas show how this little insect is coming to deserve even serious medical consideration. Army and navy hygiene are subjects of special import now, and are treated correspondingly. In general, it may be said that Dr. Bergey's book will deserve in this edition the same popularity that exhausted the last edition in about two years.

Annual Report of the Department of Health of the City of New York for the year ending December 31, 1902. Martin B. Brown Company, New York (Health Department Publication).

Health departments of smaller cities and towns not sure of what they should do to improve the health of their communities will find an ample field of suggestion in this volume. The questions of milk, hygiene, of care for the water supply, of the smoke nuisance, and other specialties, are treated in this volume, as well as the regular data of the health report for the year.

The Surgery of the Heart and Lungs. By Benjamin M. Ricketts, Ph.B., M.D. A History and Résumé of Surgical Conditions found therein and Experimental and Clinical Research in Man and Lower Animals, with Reference to Pneumonotomy, Pneumonectomy, etc. The Grafton Press, New York.

The first impression one receives on opening this rather large volume of 500 pages, is that the work has been very freely illustrated. Many of these illustrations are microphotographs, the rest, almost without exception, are photographs of gross laboratory specimens. One of the most valuable parts of this work will be found in the chapter on "Practical Hints and Theoretical Considerations." These are deduced and suggested by the author's experiments on dogs, nfty of which are fully tabulated and described in an appendix. These hints cannot fail to be of great value, not alone to practical surgeons working on the human being and to experimenters, seeking to corroborate the author's findings or to further the interests of the surgery of the heart and lungs, but to all laboratory workers as well, who are engaged in any form of research surgery on the vertebrates. The book is, therefore, to be cordially recommended to all laboratories of surgical research. The very full bibliography attached to each chapter is in itself of the very greatest use and value to all.

An interesting feature of the book is the table of terminologies, which is full and much to the point. Some such table might well be duplicated, to the manifest advantage of students, in text-books on general surgery. A commendable effort evidenced throughout the book to render the work comparative as well as human, in conjunction with the special characteristics already noted, justify the expression of a belief that the book, though not destined for wide circulation, will be welcomed and appreciated in certain rather limited circles.

A Text-Book of Physiology. By Isaac Ott, A.M., M.D., Professor of Physiology in the Medico-Chirurgical College of Philadelphia. F. A. Davis Company, Philadelphia.

In his preface the author states that his book is not a treatise but an elementary work. No attempt has been made to describe laboratory technic or to discuss electro-physiology, a subject which occupies too much space in many current works, and no time is wasted in reviewing the literature of doubtful hypotheses. The chapters on the circulation and blood are especially good, and are considered from a practical clinical standpoint. One might wish that certain subjects were treated a little more fully for examination purposes, but full references are given for consultation. The illustrations are clean cut and intelligible, the typography is good and the book deserves a wide popularity, both in medical schools and among the shelves of physicians' libraries.

Transactions of the American Pediatric Society, Fifteenth Session, held at Washington, D. C., 1903, edited by Walter Lester Carr, M.D. Reprinted from *Archives of Pediatrics*, 1903.

As the membership of this society includes the leading pediatrists of this country and Canada, the papers here published well represent American thought in relation to children's diseases. It would be too much to attempt to indicate all the papers and their authors, but, selecting at random to indicate the general trend of the articles, we might mention Edsall's Study of Still's Type of Chronic Polyarthritis; Holt's on Abscess of Lung following Acute Pneumonia; Shaw's Determination of Fat and Total Solids in Milk, and other papers on Infant-Feeding and Milk; several papers on Affections of the Newborn by Wilson, Snow, Hamill and Nicholson; and a discussion on the bacillus of Shiga by Flexner, Park, Koplik, Holt, Knox and Booker.

Essentials of Medical Chemistry. By Lawrence Wolff. Sixth Edition, revised by A. Ferree Witmer. W. B. Saunders & Co., New York, Philadelphia and London.

This new edition needs no extensive review. The work has shown itself to be useful to students. While opinions may differ as to methods of imparting this type of knowledge, we agree that for the type of work it is one of the best of its kind. It is conveniently arranged and most of the new matter of recent years is included

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 85. NEW YORK, SATURDAY, DECEMBER 17, 1904. NO. 25.

ORIGINAL ARTICLES.

DIAGNOSIS OF DISEASE IN CHILDREN.[1]

BY J. MADISON TAYLOR, A.B., M.D.,
OF PHILADELPHIA.

MEDICINE is approaching the exactitude of a science only in recent years. This is due mainly to the indefatigable labors of physicians at the bedside and in clinical laboratories, also to researches of the chemist and physicist.

Nevertheless, to the reader of medical literature there often comes a sensation of discouragement on encountering the accumulation of statements often contradictory, conflicting or unrelated, on the same lines of thought. The fault lies in approaching the subject without the exercise of a wise critical faculty attainable only through a practical familiarity with the laws of chemistry, physics, comparative biology, anatomy and physiology. It is by no means necessary that this knowledge should be full or elaborate, but the constant use of a fair and clear concept of fundamental truths, conditioning these subjects, is entirely feasible and most necessary.

Upon such a concept alone can a sure foundation be laid for progressive medical thought capable of uniform acceptance and practical results. Diversities in belief must always exist and aid in the development of truth, but in medicine these divergences are so wide and contradictory that we repeatedly fall under grave accusation of cherishing inconsistencies most hurtful to those seeking our advice. A tendency is plainly discernible now, however, among the best authorities to get back to elemental principles in forming decisions and recommendations. The one principle which must ever guide us is to think in physiologic factors in diagnosis as well as treatment.

On the subject of diagnosis a monumental literature exists testifying to skilful observation and patient gleaning among the products of wise minds, cemented by the systematic presentation of well formulated rules. Too often this resembles a towering mass of varied and suitable building material, rather than a finished and symmetrical structure evidencing skilful design. Much of this material on examination will stand revealed as a mere mass of authoritative opinions which obtain currency because of the keen observation of certain early men of genius, yet is far from exact, and much will prove to be mere variants in the history of outworn beliefs. Cherished and respected opinions of great thinkers, especially when simulating truths, have always exerted more influence on medical belief than is warranted. Our tendency is to retain these postulates of earlier teachers rather than to use, as working formulæ, the fundamental principles of growth and change, whereby alone we can do sound reasoning. We want not so much new facts, as a more practical application of those already recorded and tested, yet scattered and often unrelated truths whose efficiency is often almost lost by being locked up in large treatises, such as on physiology and pathology. The use of these treatises is largely confined to scientific specialists, and too rarely consulted by clinicians. Again our students should have no fascinating theories taught them, only well-attested facts and truths. Conjectures come to all. We need nothing in medicine more imperatively than teachers with clear practical minds who shall glean the best conclusions of reliable observers and research workers, and present these to the undergraduate in concrete systematic fashion; in tenable formulations unmarred by brilliant theories.[1] A constantly recurring error, dominating our concepts of disease, is the tendency to assume one or two symptoms as pathognomic and lose sight of the symptom-complex. A single obvious symptom may be predominant in a well-defined disease, but it may also be an expression, or characteristic feature, of many pathological processes; at other times it may be the result of previous degenerative changes, a neurosis, a psychosis, or expression of metabolic instability the result of neurotic disturbance. Indications obtained through peripheral phenomena reveal much, but conspicuously little attention is given to a study of many recognizable phenomena the immediate result of reflex disturbances in the segments of the cord. Knowledge of the intimate relationship between the arterio-motor mechanism of the organs, the nutritive centers and outlying parts of the body is needed to interpret many generic qualities of disease. Later the parts affected, or obviously disturbed, may and do require attention, but not to the exclusion of the primary or central derangement. We need broad-minded teachers who shall make clear the fundamental principles of early changes from the normal process, the governing innervation, direct and vasomotor, hence the normal variations in the blood supply, lymph circulation, cellular equipoise and, above all, the earliest evidences of divergences therefrom which may proceed so far as to merge into abnormalities producing changes recognizable as disorder, hence passing on to structural alterations sufficiently extensive to be regarded as pathologic, and finally into lesions. To do this should not tax ordinary professorial knowledge,

1 Read by title before the Section on Children, American Medical Association, June, 1904.

1 Conversation with many professors in medical schools confirms this opinion.

it merely demands a change in the point of view, keeping in mind the simple immutable laws of growth and presenting them in such a systematic fashion as shall best explain the pathologic lines of least resistance.

The subject of disease in childhood or youth can never become plain as it should till the physiologic variations between the young and the adult are differentiated for the student. This knowledge may exist, but it is seldom formulated and presented to the undergraduate. Few textbooks allude to childhood physiology except in early chapters, and then inadequately. Those of us who have grown gray using the older methods may be eagerly alive to the importance of a different standpoint of teaching, but we can not do what younger men will ere long accomplish.

In diagnosis we have been for centuries proceeding on deductive lines, amassing a vast amount of accurate information, based on, it may be, sound scientifically winnowed facts and thence advancing to conclusions more or less practical. When there are more who shall be trained to proceed inductively along the foundation levels of biology, embryology and physiology and thence ascend to pathologic planes, vastly more light will be afforded by which to apply therapeutic principles from the same sources.

We must know more of normal growth and the phenomena of development. The energy of growth is a colossal force and significant in many departments. This may be defined as the sum of all the forces determining physiologic work causing the development of living organisms (Tremoliere) potential energy exists as a heritance in the ovaries. After birth energy is required from without as well as from within. While in the adult nutrition is necessary only to supply waste of the tissues, in the growing child many conditions demand hypernutrition due to its rapid development. (Ballantyne.)

The child of rapid growth usually fails of symmetric development in several directions. Disease processes, infections, accidents of nutrition, environmental influences, etc., all tend to initiate and emphasize minor deformities. Overgrowth usually leads, for instance, to poor thoracic capacity. If the thorax is for any reason disproportionately small and narrow a variety of special predispositions are encountered. In such individuals glandular engorgements and inflammations are common and difficult to control. Pneumonia is more severe and dangerous, also pleurisy, heart disease, especially carditis, peri and endo.[1]

Inadequate gaseous interchanges aggravate disorders of both lungs and intestines; the eliminating organs are oppressed, congestions are encouraged in various parts, and oxygenation is impaired. Of the potentiality of the full functionation of the great ductless glands we know as yet relatively little. When we do know, and our means of recognizing them are better specialized, it will afford excellent grounds for legitimate inferences and useful conclusions.[1]

In diagnosis our primal purpose is to recognize and elucidate the onset of functional derangements and detect disease in any stage or form. If, however, we fail to devote sufficient attention to morbid phenomena of the mind and morals we perform less than half our duty. Disorders of the mind are dependent upon one of two factors; either defects of development in the brain, or diseased processes of the brain, or retroactively. The purpose and aim of diagnosis rests upon the concept that by the early recognition of manifestations of morbid physiology we shall thereby find means to check the changes which would otherwise pass on to destructive alterations.

If this proposition obtains for the disorders of the physical functions how much more must it fulfill a valuable service for those of the brain which is a far more sensitive structure and especially liable to permanent damage form slight irritation. It is a great privilege, to mitigate bodily suffering, to limit the progress of structural degenerations, to prevent disablement and save life, but how vastly higher is the prerogative to turn aside those perils which jeopardize the budding intellect and rescue a tottering moral nature. Yet how little of this subject is the student taught, or again how much interest does the average practitioner display in this incomparably higher phase of his duties?

It should be the aim of the clinical teacher to emphasize unceasingly the urgency of obtaining the earliest possible indications, omens or prefigurements of departures from normal functionation; especially in children. When this is accomplished the greatest economy is effected; first, in the limiting of suffering and the progress of disease, and second, in forefending the organism from developmental defects. All life is a process of development but the effects of interferences are vastly more forceful and significant in the young. Diagnosis and symptomatology, as ordinarily presented, is adjusted to meet the requirements of well developed disorders with only secondary reference to the phenomena of onset. There is room for much useful research along the lines of prodromal and the first obtainable characteristic morbid phenomena. True it is that some of these early omens are not conclusive, but certain of them are more significant than credited. Certainly greater attention may be well bestowed upon their formulation and emphasis, for here are many of our triumphs or blunders to be made, unless our defects are mercifully condoned.

Diagnosis of the morbid condition of child-

[1] Woods Hutchinson's researches on the thoracic index are most suggestive. Jour. Am. Med. Assn., May 2, 1903.

[1] Charles De M. Sajous has done great things to make this clear and leaving out the significance of his conclusions, still his book teaches us to think physiologically on growth and change. The second volume of "The Internal Secutions," with the contents of which I am familiar, will supply invaluable data by which we may learn to reason more soundly.

hood involves something more than a mere search for evidences of disease. During the period of plasticity numerous influences prevail in all ranks of life to alter normal growth and organic development by which the foundations of constitutional weakness are often laid. These are in a great measure, preventable, at least in part. It is the duty of the physician to recognize and promptly rectify the evil effects of environment and training, and in so far as possible of inheritance. Hence it is the most important department of differentiation to possess clearly defined standards of growth, proportion, activities, sensitiveness, functional competence, intelligence and capacity for endurance. These standards should be the products of wide observation, reading, and experience, among normal as well as abnormal conditions, but unless tempered by judgment of a higher order, right conclusions are not assured. It should be the duty of clinical teachers to formulate prototypes which may obtain certain recognition. A careful presentation of the anatomy of childhood should be always offered; there is little enough in literature.[1] We can know little of the essential nature of childish ailments till these needs are better supplied. No heaping up of scientific facts along the lines of bacteriology, pathology or symptomatology can compare in practical utility to an equipment in applied physiology based on comparative embryology.

As physiology is generally taught it serves a limited purpose but when once the student realizes that practical thinking in pediatrics can only proceed from a use of the principles of embryology our concepts will be clearer.

The standard for each pediatrist is the ideal child; a composite picture of normal children, and cannot be formed too carefully nor from too thorough an interpretation of the data at his command. Next to the ideal child the diagnostician must erect for himself examples of permissible variants. In considering the broad subject of disease in the young, at least in America, we must not limit ourselves to children of pure Anglo-Saxon stock but hold in view the many other racial characteristics with which we are likely to come in contact.

Again, there are the crosses of Latin, Celt, Slav, German, Hebrew and other white races; also the hybrids of red, yellow and black races. These modifications exhibit laws of their own, as yet by no means clear, but deeply significant.

Inheritance of tendencies is recognized as a potential factor by most authorities. Where doubts obtrude on the mind of the clinician, as they inevitably must, the safe course is to read the latest teachings on the subject of inheritance and heredity and sift out the acceptable conclusions. Predisposition to disease is an obvious factor, admittedly forceful for harm.

1 Among the best are those of George McClellan, Symington and J. W. Ballantyne. There is no systematic physiology of childhood in English. Scattered facts exist on both these subjects but they might be better correlated.

Difficulties of diagnosis are many enough among children normal in structure, in neural balance and in mind, but these grow greater where constitutional variations or deviations are present. Hence it is desirable to consider variants of types; peculiar and exceptional children. The normal processes are profoundly modified by peculiarities of temperament due to inheritance or acquired. This subject would demand, for full consideration, much space, but it will suffice here roughly to outline the salient points. The most valuable and suggestive literature I have found is that which emanates from the studies in childhood psychology instituted by E. Stanley Hall. An article by E. W. Bohannon covers the ground sufficiently to warrant using his classification, and though the study is more psychic than physical it is most helpful in diagnosis. The psychic factor as stated, demands deeper attention in clinical medicine, especially among children, than ordinarily obtains.[1]

The number of those studied by Bohannon was necessarily limited but covers over 1,000 individuals, enough from which to formulate certain types of mental and physical conformation. These types are the heavy, the tall, the stout, the small, the strong, the weak, the deft, the agile, the clumsy, the beautiful, the ugly, the deformed, those with birth marks, the keen and the mentally precocious, those with defects of sense organs or mind, the nervous, the clean, the dainty, the dirty, the disorderly, the obedient, the disobedient, the orderly, the teasing, the buoyant, buffoons, the cruel, the selfish, the generous, the sympathetic, those with imagination, the liar, the ill-tempered, the silent, the dignified, the frank, the loquacious, the inquisitive, the courageous, the timid, the whining, the "spoiled," the gluttonous, and the "only child in a family."

Many of these types cross; several are liable to include similar features, constituting composites of the types, making the study most complicated if carried to legitimate conclusions.

A review of Bohannon's findings and conclusions from the observation of this large group reveals much of practical interest to the clinician. It is manifestly impossible to discuss all, but confining ourselves to a few words about those types in which the physical features are dominant will prove of value. As to general health and mental ability there appears good reason for believing that the larger children, except the extremes, are superior to others. But it must not be forgotten that there are pathological cases in the group, especially in those showing marked departures from the average. Leaving out of account possible tendencies to acromegaly or myxedema they suggest a too early maturity. They are generally even-tempered.

Small children evidence delayed development. The less vigorous show degenerative phenomena, many are "delicate," ugly, deformed, or vicious,

1 The recent book by E. Stanley Hall on "Adolescence" deals fully with the subject.

dull, mean or spiteful and tend toward morbidity. The strong children, while exhibiting many admirable qualities, are likely to be aggressive, harsh, course, rough. More is expected of them, hence they are often exhausted by compulsory work; their offenses are the result of excessive, often explosive, energy. The weakly children are likely to show pronounced evidence of degeneracy, often they are ugly and deformed, cruel and mentally deficient. Inheritance was not so frequently recognized a cause as parental follies, especially during the embryonal period. Temperamentally they are usually unfortunate.

The deft and agile show better health, yet are undersized. Clumsiness is found due to two causes; first, of want of development of the mechanism which functions the accessory movements; and, second, excessive inhibition of the same along with lack of emotional balance. Ugliness is usually accompanied by many evidences of degeneration physical and mental; in the deformed these deviations are even more decidedly present. Deformities are largely *ipso facto* manifestations of deviation, defects of central development exhibiting anatomic and physiologic faults, some of which are remediable. Under good care many of these improve greatly, some becoming fine adults. They are found to be treated with amazing lack of consideration by parents and associates, hence they suffer temperamentally.[1]

Among those showing defects in mind, sense organs and speech, there is much to indicate a general decline. They are morbidly retiring, dependent, and lack symmetrical development in part due to original defects and deficiencies in normal stimulus.

Those children grouped as "nervous" exhibit delicacy and instability of constitution; they lack size and vigor, are timid, sensitive and changeful, disposed to be irritable and meddlesome, lacking in control, hence untruthful. The extremely overdainty and the distinctly dirty, each excite suspicion of mental abnormalities. Buoyancy and teasing both indicate excess of energy; so also of cruelty, but here ancestral traits seem manifested.

Lying and imaginativeness are allied, and point to lack of self-control or selfish imitation; the associated traits are disobedience, ill-temper, thieving and bad health. Those who are peevish, untruthful, discontented, are usually of delicate make and evince instability and poor vitality. Those who are loquacious, voluable and inquisitive, lack inhibition.

Courageous children are usually healthy and strong in mind and body. Timidity has a physical basis, but may be acquired from bad environment. The "only child in the family" in 66 per cent. shows disadvantageous traits; they are usually of poor health, lacking much of normality, both mental and physical.

The "youngest child" the "only boy" or "the only girl" display many striking resemblances to the "only child." The value of such conclusions from a statistical study is very great; especially when it is noted that the writer started out with the expectation of arriving at, in many directions, radically different conclusions.[1]

In the examination of children next to a trained observation the most necessary item of skill lies in palpation. Extensive experience is needed to acquire this facility. Long years are not so efficacious as the consciencious use of every opportunity offered. Tactile sense grows rapidly if undivided attention is given to a few cases; more are better, but carelessness and guess work are liable to follow redundant advantages. Estimation of resistance, the tone of tissues, skin and subcutaneous structures, conditions of overcontraction or relaxation, temperature and the like are often of deeper significance in the infant than in the adult. Size and relationship of abdominal organs can thus be more accurately learned than by percussion, which in the very young is of less than secondary importance; indeed often misleading. The left hand, in right-handed persons, should preferably be trained in tactile acuteness. The hand should be laid down, quietly and gently, flat upon the part with a lingering touch permitting an appreciable amount of time to elapse for sense impressions to grow and become deliberately interpreted, imitating the methods of the blind. Much can be thereby learned not readily reducible to language yet helpful to conviction. Pure touch is suggestive, but a combination of contact and manipulation, supplemented by slow, tactful pressing and relaxing, reveals far more. So much concerning the areas usually explored by palpation, such as the abdominal and thoracic viscera, but much can be learned by the hand applied to all parts of the body, an act too rarely practised by physicians, and not thoroughly by some surgeons, whose search often involves less thoroughness than it might.

The consistency of the skeletal structures, particularly those adjacent to the vertebral column, will afford evidence of great value later to be defined. A highly significant phenomenon is the quality of resistance in the muscles, such as those of the neck in many conditions, both physical and psychic. Few children are too young to betray at some time or other rigidities, transient or protracted, yet significant of alterations in tissue from lymph stasis, nerve irritation or psychic exaltations or depressions. The educated hand is not employed to the extent it deserves in search

1 Boys are more liable to deformities than girls. Warner's Studies of London School Children, showed that the proportion of physical anomalies of boys was 8.27 per cent. to girls 6.78 per cent. Again, according to Newsholme (vital statistics, p. 61) the males outnumber the females in stillbirths, probably owing to the greater difficulties at birth. Thus in ten years, 1865 1875, there were in France, 144; Italy, 140; Belgium, 135; Sweden, 133, and in Prussia, 129 male, to every 100 female stillbirths. This seems to throw light on deformities incident to difficulties in labor; also thus intra-uterine disturbances are much more likely to occur with boys than girls. (Bohannon).

1 It is impossible here to review Bohannon's "Interpretation of data," but this is highly recommended to those who would get a fair idea of inheritance and heredity, both of physical and psychic traits. (See Pedagogical Seminary, October, 1896.)

for collateral data in organic disturbances and particularly where, as is common, the psychic state has contributed to induce excessive tensions or relaxations. In adults emotional disturbances often produce conspicuous hypertensions gravely affecting the continuance or exaggeration of lesser physical derangements which are happily often entirely relievable, mainly by teaching the sufferer to let go and relax. To a less, but appreciable degree, this obtains also among children and cannot be ignored. In acute diseases one often finds that pain is present, local or general, not so severe as to cause a cry perhaps, but merely altered sensitiveness beyond the degree of discomfort, and manipulation often relieves this to the extent that symptoms modify, sleep follows, temperature drops, etc. Abdominal organs frequently grow tense from gaseous distentions and skilful manipulations over the distressed area often relieves this, or gentle pressure may be applied over the lower dorsal or lumbar region; muscles may ache, nerves become tender from retained toxins and thus limbs or back, but especially the deep structures of the back or neck, become hypersensitive to the pressure and contractures arise.

It would seem admissable that few or no disease processes can exist in the body without manifesting themselves by disturbances of the nervous mechanisms of the area or parts involved.

These are brought about by changes in the circulation of central nervous system. A large part, by far the greater proportion of the nervous mechanisms of the body are located in the spinal cord. Again, disturbances of the circulation in the spinal cord have been found to be expressed externally by alterations in the conditions of the tissues supplied by the posterior primary divisions of the spinal nerves, as well as in the peripheral parts diseased.

A recent and most important contribution to the study and elucidation of disease, has been made by the observations of John P. Arnold and published in the *International Medical Magazine*. As demonstrator of physiology in the University of Pennsylvania, he made special researches on the clinical significance of the inter-relationships between the blood supply of organs and their functual activities, and claims to have systematized our knowledge of the vaso-motor mechanisms. This method of diagnosis is based upon rational physiological principles of much utility, not only of and for itself, but confirmatory of data gained through other avenues. Oftentimes by this method much can be learned more helpful in outlining treatment than through any other sources, because explanatory of the character of the derangement and on broader principles, supplementing facts learned otherwise.

He points out that there is a compensatory relationship between the circulation in the tissues of the back, lying adjacent to certain areas of the cord, and the circulation in the local segments.

Elaborating these observations he has been able not only to modify acute and chronic ailments, often to an extraordinary degree, but has also evolved a system of diagnosis. This last is so helpful that, when perfected and amplified by clinicians, it seems destined to offer a more exact and yet simple means of estimating the nature and extent of derangements than is afforded by many of our commonly accepted means of physicial exploration, as well as supplying important therapeutic possibilities.

Thus the phenomena of disease are studied from the standpoint of the central nervous system and not only from peripheral phenomena.

This department of symptomatology is still in its infancy, and even in the hands of enthusiastic experts can as yet only reveal indications. More accurate specifications and gradations can be reached in proportion to the personal equipment of the observer in physiologic knowledge and the natural history of disease. When clinical phenomena shall be interpreted more closely along physiologic lines and this principle recognized and employed by a larger number, we may expect records of refinements and exactitudes revealing many facts hitherto unattainable.

The principle on which this system of diagnosis is founded is the well established fact, familiar to physiologists, but not yet applied by clinicians, that a reading of the viscero-motor and other activities must be sought through a comprehensive knowledge of the vasomotor mechanisms, and the spinal segments from whence a viscus is controlled.

Much importance is ordinarily attached to the agency of the sympathetic nervous system. When, however, it is borne in mind that this system is a mere outgrowth from, and entirely secondary to, those centers in which impulses are initiated and controlled, we must approach the subject of organic and other derangements with the significance and responsibility of the centers in the cord and in the various segmental combinations, kept constantly in view. The prevailing belief as to the source of the functions of the sympathetic is well illustrated by M. Duval (Sajous) who says, "It is now recognized that most of the nervous phenomena of the visceral functions have the spinal cord for their centers, and that even for its vasomotor functions the sympathetic nerves utilize only borrowed power originating in the upper portion of the spinal axis; the same obtains in respect to its influence upon the heart, and also with most visceral reflexes, the centers of which are in the cord; so that even the expression sympathetic system to-day means nothing."

Further, effects upon the blood supply of all parts of the body can be wrought by influencing the centers in the spinal cord more directly and simply, and through them exerted upon the sympathetic centers and ganglia, than from measures directed to the organs disturbed. Per contra, disturbances in the various organs, systems, and tissues, being due to circulatory changes induced

reflexly upon the central nervous system, the major portion of the nervous mechanism being located in the spinal cord, disturbances of the circulation in the cord are expressed by alterations in the structures of those parts supplied by the posterior primary divisions of the spinal nerves, as well as in the part affected. It is then to be inferred that local changes will be manifested in the tissues of the back along side the vertebral column. During the continuance of diseased states, or lesser disturbances, pronounced alterations are to be observed in those tissues immediately innervated by fibers arising in the spinal segments whose integrity is disturbed by the derangements in function of organs and areas dependent upon those segments. In brief there is both a nutritional and sensory reaction exhibited upon the erector spinæ muscles, and allied structures, caused by the disturbed circulatory equilibrium in areas depending for vasomotor regulation on certain groups of segments of the cord. There is, as has been said, a compensatory relationship existing between, first, the surface muscles and the skin supplied by the posterior primary divisions of the spinal nerves, and second, the blood vessels of the cord and the deep structures, organs and remoter parts innervated by fibers whose cell bodies arise in that region of the cord.[1]

Almost nothing is to be found in the literature of clinical medicine which directs attention to the varying conditions of the structures of the back. Orthopedists seem to confine their observations chiefly to the gross conditions of the ligaments, muscles and bones. Neurologists take little account of the gross status of tissues, other than those showing alterations, motor or sensory.

Irregular practitioners of one type or another have, from time to time, attached much significance to the status of the ligaments and attitudes of the vertebræ. "Dislocation of the bones of the back," as a common cause of functional derangement, is not for a moment to be accepted. The highest authorities on anatomy state that, except when long standing or progressive disease processes have been the cause, as in aggravated "lateral curvature" or tuberculous disease, changes in relationship of the vertebræ are practical impossibilities. Relaxation of the lateral and posterior spinal ligaments, due to nutritive faults, produces often the appearance of dislocation, but these phenomena disappear by restoration of the tonus of the shrunken tissues, chiefly through mechanical stimulation.[2] Thus, any agent which causes vasoconstriction in the nerves and muscles of the back, contiguous to the spinal column, will produce, per contra, dilatation of the vessels in the cord, and of the organs and parts beyond in the line of innervation.

Any agent which produces dilatation of the blood vessels supplying the tissues of the back will, by compensatory action, induce constriction in those of the cord, and beyond parts. The significance of this is at once made plain and its value manifested not only as a factor in diagnosis, but in treatment.

The element of doubt which can be urged against this view, is not that the especial conditions to be described actually exist. Highest physiologic authorities can be cited to prove the first, but whether this alteration in the tissue resistence or vaso-tonus can be demonstrated to such an extent as will produce any practical results in either the muscles, or more potently, in the functional status of the organs and peripheral parts, depends upon the evidence of clinical results. This is amply demonstrated to those who have studied the question practically.

It is plain to the perceptive hand that these muscles are affected, and according to definite laws of innervation, showing conclusively that where certain organs or parts are deranged, the corresponding muscles do show these changes. Again, where these muscles exhibit characteristic changes there are assuredly derangements in the organs and tissues corresponding to the innervation.

Again in the normal individual these compensatory conditions are not conspicuous, but where there is a definite derangement the evidences are obvious and clearly demonstrable, and most helpful in diagnosis.[1]

Dr. Arnold formulates certain generalizations which are to be noted upon a careful survey and palpation of the back. On inspecting the back of one who is, and has always been, perfectly sound there will be seen (if certain attitudes are assumed to bring them into prominence), the spines of the vertebræ in normal alignment, distance apart, and degree of posterior projection. If there has been a history of long continued or recurrent disturbances of the internal organs these are frequently revealed by alterations in the tonus of the blood vessels of those muscles and other tissues innervated by, or lying adjacent to, the governing segments of the cord from which the organs at fault are reflexly controlled through their vasomotor connections. The form change exhibited is an atrophy of some, infiltration and thickening of others; and if long continued by asymmetries of the vertebræ, the spines apparently pointing in different directions. If the lesions have become chronic the spines are found separated, due to relaxation of the posterior ligaments, until between two or more marked depressions appear, or several are depressed below the normal line of projection. This disor-

1 The spinal cord viewed from the embryologic standpoint is a cylindrical tube of nervous tissue made of the fusion of bilateral ganglia in some of the lower worms. This view of the spinal cord is essential to the proper concept of the nervous mechanisms to man and the higher animals.

2 Attempts to "replace" these so-called "dislocated bones" and to relieve pressure on nerves, the creed of the osteopath, sometimes results in benefit, not by accomplishing the object aimed at, but through effects wrought upon the centers of vaso tonus and lymph activities by mechanical or other stimulation. Where, as sometimes happens, undue force is used to "pull or push" these tissues in place, harm is often wrought of which little is said, or to which other causes are assigned.

1 It must be said, however, that unless the observer possesses more than the average tactile acuteness, nothing will be noted except certain gross infiltrations or atrophies. Persistence will be rewarded by soon achieving much satisfactory information.

ganization of the vertebræ is more apparent than real, the asymmetries being due to loss of tone and relaxation in the supporting ligaments, will disappear later as is proved by a prompt restoration of alignment under appropriate treatment. In children, even very young ones, these phenomena are readily noted as has been done for two winters in my clinic at the Children's Hospital, where certain fourth-year medical students beside my assistants, usually four in number, have acquired much dexterity in detecting these changes.

The examination of the patient should be made while lying on the side and facing the operator with the head slightly elevated and all the limbs so arranged as to secure the utmost relaxation of the tissues of the back. The palpation is made by the cushions of the examiner's fingers lightly placed over the structures next to the line of the vertebræ. He draws them gently upward and downward to and from the vertebral column an inch or two, rolling the muscle fibers under hand, and carefully estimating their density, elasticity, and separability; with just enough pressure to determine resistance and sensitiveness. After gently palpating the entire length of one side of the spinal column the patient is turned on the other side and the examiner again facing the subject the corresponding tissues are studied in the same way. Finally the patient assuming the dorsal decubitus, the examiner stands at his head and the lateral and posterior tissues of the neck receive attention.

In most acute conditions and exacerbations of chronic states there exists more or less hypersensitiveness in the tissues adjacent to those segments of the cord corresponding to the areas in which there is disturbed innervation. Alterations are found also to an even greater extent in the muscle fibers, due to infiltration, thickening, etc., producing a cord-like condition which slips back and forth under the palpating fingers in a manner resembling tendons or strands of muscle in tension. In places also the structures will occasionally be found to have lost tone to such an extent as to feel like dough, or, through atrophy, may seem absent. In acute conditions, like catarrhal disorders of the mucous membrane of the head, stomach, intestines, bronchi or of the genito-urinary cycle, the tenderness is often marked in certain definite regions disappearing promptly as recovery follows. During the progress of pneumonia and bronchitis the tenderness is rather less but the infiltrations are perhaps greater. In acute disorders of the genito-urinary organs moderate tenderness is observed over the lumbar areas and especially over the sacral nerves.

These sensory phenomena are less common in children than in adults if pain is a feature of the malady. Gentle pressure over the tender spot, at first disagreeable, soon produces relief and is welcomed; in some states relieving the pain or discomforts markedly and promptly. So in acute disturbances of the throat, nose and larynx, in addition to the sensory disturbances, changes in resistance in the upper dorsal areas are noticable as well as in the muscles of the neck. Personally I am not confident enough of my observations as yet to specify the precise significance of all the changes noted because there is much individual skill required to differentiate or interpret findings, but have already derived much practical information by this means, and as my skill grows I regard it with increasing favor.

To make use of this method of diagnosis requires a systematic reading of clinical facts in the light of broad physiological principles. Since few students are adequately grounded in this, it requires a readjustment of knowledge and careful study of the border land of physiology and pathology.

In a personal communication Dr. Chase Lester Leonard has given a résumé of the diagnosis possibilities of the Roentgen rays in disease in childhood.

The Roentgen rays have found many valuable applications in the diagnosis of children's disease. The skiagraphic method is, of course, more accurate than the fluoroscope, since it introduces less of the personal equation. The fluoroscopic method is practically adapted to the examination of children as they are more readily agitated. It, however, finds its greatest value in detecting abnormal movements, or absence of movements, such as restrictions of respiratory action in the diaphragm. This restriction in motion is seen where the normal capacity of the lung is altered either by congestion, consolidation, abscess or pleuritic effusion. It also determines their location as the darkened area contracts sharply with the normal lung, which is less opaque, and alters with inspiratory movements when the greater mass of air makes it appear more translucent. The more accurate detail afforded by the skiagraph is essential in locating accurately abscesses in the lungs and circumscribed pleuritic effusions. It also affords a better idea of cardiac enlargement. In purely medical conditions the results are a marked addition to our method of making a diagnosis. In surgery it affords more accurate diagnosis than can be obtained by other means. Thus the exact extent and character of congenital bone defects, or malformations, is determined and they are differentiated from pathological processes, as coxa vara are easily differentiated from simple congenital dislocations.

The contrasts afforded between diastasis, dislocations and fractures are also of greater utility. The ability to detect renal, ureteral and vesical calculi is a marked advance in precise diagnosis. The exact size and position of the calculus can be thus determined without passing a sound or subjecting the patient to any chance of infection. These calculi can in this way be detected as soon as a suspicion points to them and before they have done irreparable injury and before the symptoms have become so marked as to be otherwise readily determined.

SYMMETRICAL ENLARGEMENT OF PAROTID AND LACRIMAL GLANDS—NODULAR IRITIS.[1]

BY COLMAN W. CUTLER, M.D.,
OF NEW YORK.

THIS case is offered as an example of a very rare condition, and in conjunction with the deposits in the iris, it is believed to be unique:

Case.—October 11, 1903: Sophie Ferguson, colored, age twenty years, cook and laundress. Her home is near Norfolk, Virginia, but she has lived for more than a year near New York. General health has always been good, no severe illnesses, no history of malaria or of pulmonary diseases, nor of syphilis. The family history is negative.

For about one year she has noticed a swelling in front of both ears which for six months or more has seemed to her to be unchanged in size. It has always been painless. The swelling of the lacrimal glands has attracted her attention recently. About four months ago she noticed that the right eye was irritable; it was not painful or bloodshot, but there has been occasional neuralgic pain in the temples, especially of the right side. Vision in the right eye has failed.

Examination.—Both parotid glands are enlarged, with even, smooth surface and firm consistency. Not tender on pressure, and the skin is freely movable over them. Their dimensions are:

Right parotid: Greatest anterior posterior.9 cm.
Greatest vertical .....7 cm.
Left parotid: Greatest anterior posterior..5 cm.
Greatest vertical .....7 cm.

The protrusion of the glands is very noticeable. Both lacrimal glands are palpable below the orbital margin, filling upper and outer thirds of lids nearly to outer canthus. They are firm, lobulated, rather uneven masses. The submaxillery glands are somewhat enlarged. Cervical, epitrochlear, preauricular and inguinal glands are just palpable. Mouth is normal, mucous membrane pale. Liver and spleen not enlarged, ovaries apparently normal. Mammary glands normal. Examination of lungs is negative.

Examination of eyes.—Conjunctivæ normal. O.D. slight ciliary injection, cornea rather dull with surface slightly roughened, with a very fine granular appearence of the stroma. Numerous small precipitates on Descemet's membrane. At the angle of anterior chamber are six or seven nodules smaller than the head of a pin, of yellowish or pale pink color. Some of these nodules have a fine vessel winding around or over them They are arranged close together, and to some extent are confluent. Several very small white points protrude from the surface of iris, but otherwise its stroma appears normal, brown, with markings possibly a little blurred. Several fine posterior synechiæ. Tn. Lens clear, vitreous, hazy. Fundus not seen.

[1] Read at Academy Ophthalmological Society, July 14, 1904.

O.S. Cornea, fewer precipitates, no synechiæ, Iris, vitreous and fundus normal.

Vision O.D., 20/200; O.S., 20/30.

Urine: Normal.

Blood examination, October 29, 1903, by Dr. J. T. Gorton: Hemoglobin, 9 per cent.; red cells, 4,352,000; white cells, 5,200.

Differential count—

	Per Cent.
Polynuclear neutrophiles	59
Large lymphocytes	15
Small lymphocytes	22
Eosinophiles	0
Basophiles (mast cells)	2.7
Transitional forms	1.0

Blood examination, November 23, by Dr. F. C. Wood: Hemoglobin, 70 per cent.; red cells, 4,730,000; white cells, 5,900.

Differential count—

	Per Cent.
Polynuclear neutrophiles	65
Large lymphocytes	18.5
Small lymphocytes	7.5
Eosinophiles	3.0
Basophiles (mast cells)	1.5
Transitional neutrophiles	4.0

Dr. Wood writes: The result of the blood examination is entirely negative, except for a slight anemia. The proportions between the leucocytes are quite within normal limits."

The patient remained under observation for two months; during this time the parotid tumors became a little smaller, the lacrimal glands remained the same. The iris in the right eye showed slight changes from time to time, the tumors in the angle becoming larger, and the protrusions from the surface more numerous; the white dots on the dark iris presented a very striking appearance. In the left eye, several small nodules appeared in the angle of the anterior chamber, and although no white points were visible in the surface of the iris, there were several places where the tissue protruded as if nodules might appear.

The treatment was at first iodide and mercury in increasing doses, then arsenic, increased to 15 drops of Pearsons's solution, and maintained at that until the limit of tolerance was reached, and finally pilocarpine given in full doses. The parotids, and the eyes for briefer periods, were exposed to the X-rays, but without noticeable improvement. During the administration of iodide and mercury the condition of the iris grew steadily worse, the exudates on D's membrane more numerous, and also the protrusions from surface of iris. Under large doses of arsenic the condition appeared to improve somewhat, and she was advised to continue that treatment after her return to her home. Dr. B. R. Kennon, of Norfolk, very kindly examined the patient July 13, 1904, and writes as follows: "The small projections on the iris are very few in number, but both irides are bound to the lens by many points of adhesion. The cloudiness in the cornea I cannot make out to be confined

to Descemet's membrane, but seems to be in the stroma as well. She states that the parotid glandular enlargement has markedly decreased, and now there is but slight enlargement there. I cannot make out any lacrimal glandular enlargement."

It will be well to consider first the symmetrical enlargement of the parotids and lacrimal glands. This condition was first recognized as a disease by Mikulicz in 1888 in the *Berliner klinische Wochenschrift,* and more fully described in Billroth's Festschrift in 1892. In this case, also, the blood was normal, the spleen and lymph glands not enlarged. The disease made itself manifest by symmetrical swelling of parotids, submaxillary and lacrimal glands. There was in addition glandular swelling in the roof of the mouth. About two-thirds of the tissue of the swollen lacrimal glands was removed, as they were the cause of the greatest annoyance to the patient, but the tumors returned in a short time. A second time a more radical removal was made, and until death from appendicitis, three months later, there had apparently been no return. The microscopical examination showed that the tumors were composed almost entirely of small round cells among which the acini of the glands were intact. Histologically, they might be lymphoma or lymphosarcoma. If the former, one would expect enlargement of the other glands or of the spleen, and the latter would certainly show a more malignant character.

In 1889 Haltenhoff and in 1891 Fuchs each reported a similar case. In that of Fuchs the portion removed was composed of lymphoid tissue. It remained practically unchanged in spite of arsenic, which was not well borne, during a period of fourteen months. In Haltenhoff's case the tumors disappeared spontaneously or with syrup of the iodide or iron, in less than a year. Fuchs saw two other cases in all respects like the first of Mikulicz, but less pronounced. The tumors diminished after the continued use of arsenic for months. These are mentioned by Mikulicz but, so far as I know, have not been reported in detail.

In a paper by Kümmel (*Mitteilungen aus dem Grenzgebiete der Medicin und Chirurgie,* 2, 1897) 21 cases are listed which correspond in some respects to these. If we exclude those with leucemia and those in which the lymphatic glands are generally enlarged, there remain 14 cases in which parotids or lacrimal glands were swollen, and in seven cases both parotid and lacrimal glands were involved. The prognosis has been favorable. The tumors disappear, as a rule, in from a few months to two years under treatment with iodide or arsenic. After complete extirpation they have not tended to return. With regard to this fact Kümmel and Axenfeld made the following observation:

"The absence of relapses after complete removal of the glands is important in separating this disease from lymphosarcoma and pseudoleucemia, in both of which diseases relapses are to be expected."

Since in our case there has been no examination possible of the tumors, it is not easy to classify it, but clinically it corresponds to the cases of Mikulicz and Kümmel rather than to that of Axenfeld (*v. Graefe's Archiv,* Bd. 37) and others where there have been lymphomata in the orbit, and in the most varied localities. The assumption is that in such cases the exciting agent has been brought by the blood or lymph channels, while in the cases in which the growths have been limited to the parotids and lacrimal glands, the access to the glands has been through the ducts, from the mouth and conjunctiva; this is probable in a recent case reported by Baas (*Zeitschrift für Augenheilkunde,* September, 1903).

In our case, however, there is the limitation of the new tissue to the parotid, submaxillary and lacrimal glands, but in addition a uveitis of so unusual a form that the diagnosis cannot be made with confidence.

Such a uveitis, however, is of endogenous origin, syphilitic, tuberculous, lymphoid or from some infection not at present to be classified.

Millée and Vidaur (*Le Progrès Médical,* Tome 16, October 25, 1902) report a case of double dacryoadenitis with double iritis: Male, aged forty-two years, woodcutter. The patient complained of a firm, movable, painless swelling in the upper outer part of both orbits, noticed ten days before he was first seen by the authors. Eight days later an acute attack of iritis occurred with numerous synechiæ and two little "papules, reddish yellow in color, size, the head of a pin in the lesser circle of the iris." There was also a papular eruption of the skin. These symptoms responded promptly to vigorous antisyphilitic treatment. This case is interesting only because it combines the lesion of the lacrimal glands with iritis, but the etiology puts it in a different category as our case was of a chronic, indolent nature, and, moreover, it grew worse under antisyphilitic treatment.

The literature of tuberculous iritis is very extensive. Leber has described cases under the title of "Attenuated Tuberculosis of the Eye" (Bericht der ophthal. Gesellschaft, Heidelberg, 1891), which are striking in their fluctuations and tendency to spontaneous disappearance, and which, clinically, must have resembled the present case in many respects. Also, the appearance of the iris in our case is not unlike some cases of inoculation tuberculosis.

Stieren (*Johns Hopkins Hospital Bulletin,* November, 1901) reports a case of dacryoadenitis and conjunctivitis with general tuberculosis, and gives a review of the contributions to that phase of the subject.

Gallasch (*Jahrbuch für Kinderheilkunde,* Neue Folge, VII Band, 1874, p. 87) reports a case of a leucemic child with, among many other symptoms of leucemia, extreme enlargement of tear

glands and parotids. It is interesting to note that the microscopical appearance of the glands was strikingly similar to that of the case described by Mikulicz and others, in which there was no suspicion of leucemia.

Shoemaker (*Annals of Ophthalmology*, July, 1904) reports a case of bilateral enlargement of the lacrimal glands, with a discussion of the nature of that and related conditions.

Michel, in 1881 (*v. Graefe's Archiv*, Bd. 27, 11, p. 256), described and depicted most clearly, a case of pseudoleucemia which seems to have a striking similarity, as regards the appearance of the iris, to that under discussion. Michel considered the tumors in the iris to be lymphomata in a late stage of the disease, because of the fibrous character of the cells, combined with the new lymphoid tissue.

If the symmetrical enlargement of the glands and the uveitis are to be brought into the same category, we are justified, in view of Michel's case, in considering them both as a manifestation of lymphoid activity, due to some unknown agent circulating in the blood.

Häckel (*Archiv für klinische Chirurgie*, Band 69, p. 191) describes an interesting case in which the patient who had suffered a severe injury to the kidney, to which, however, no etiological significance is given, developed a severe enteritis, associated with symmetrical enlargement of the parotids and lacrimal glands. Häckel classes these latter conditions together.

It is obvious that the symmetrical swelling of the tear glands and parotids occurs in a group of cases by itself as an idiopathic condition, and it is believed by Mikulicz and Häckel that this group is an infectious disease in the broadest sense of the term, although no organisms have been found by the most careful search in the glands or blood.

In another group the same symmetrical enlargement occurs in conjunction with leucemia and pseudoleucemia, and the modern tendency is to attribute these diseases, also, to a bacterial origin.

In our case the iritis is an additional, and it would seem, a conclusive argument in favor of the bacterial origin of the disease, whether we classify the condition as pseudoleucemia or not, which is, after all, a mere clinical way of begging the question.

The tendency of our case seems to be toward recovery, as is shown by Dr. Kennon's recent report, already quoted. The limitation of the lymphoid tissue to parotids and lacrimal with a relatively good prognosis, points to an essential disease in which the growths are influenced by the functional activity of these organs, as in mumps, or else the result of infection, as is suggested by Mikulicz and Häckel, and to this view the iritis with its sluggish course, and fluctuations coinciding with those of the glands lends the strongest possible confirmatory evidence.

OVERLAPPING THE APONEUROSES IN THE CLOSURE OF WOUNDS OF THE ABDOMINAL WALL.[1]

BY CHARLES P. NOBLE, M.D.,
OF PHILADELPHIA;
SURGEON-IN-CHIEF, KENSINGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

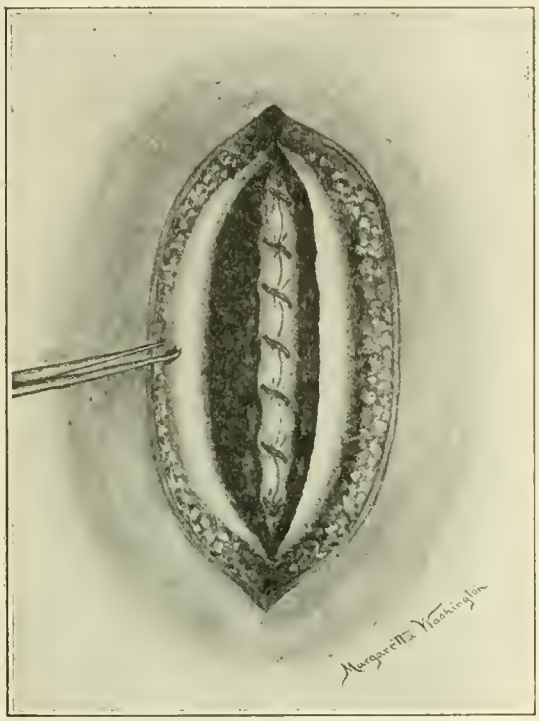
It is my desire to bring to the attention of the Society the importance of overlapping the aponeuroses in the closure of all wounds of the abdominal wall, no matter what the location of the particular wound may be. The principle is equally applicable to incisions in or near the median line, to lateral incisions whether made for operations upon the stomach or gall-ducts, or for operations for appendicitis, or for incisions in the groin, whether these are made in the operation for shortening the round ligaments or for the cure of hernia. This principle I first applied in operating for an umbilical hernia April 7, 1894, and since January, 1897, it has been applied as a routine practice in the closure of all wounds of the abdominal wall, no matter what their nature.

It is now a generally received principle that the proper closure of incisions in the abdominal wall involves the union of homologous structures, and it is almost as generally accepted that this is best secured by the employment of the tier or étage suture. There are still surgeons who claim that equally as good results can be obtained by means of the through and through suture, but the claims of these are contrary both to the theoretical considerations involved and to the general experience of the profession. While the object of the suturing of incisions is to bring the homologous structures of the wound in apposition and to restore the abdominal wall to its original anatomical relations, it is nevertheless true that from the standpoint of the prevention of hernia the most important point is to secure firm union of the aponeuroses; because the strength of the abdominal wall, from the standpoint of resisting intra-abdominal pressure depends more upon the integrity of the aponeuroses and fasciæ than upon the union of the other structures involved. This proposition is so generally admitted that it is unnecessary to adduce evidence in its support. The problem then is as to the best manner of suturing the aponeuroses to insure firm union of these structures. The usual method advised is to suture these structures either with a running or interrupted suture so as to bring the cut edges in apposition, as is done with the peritoneum, muscle, fat and skin, and this method has given admirable practical results. When it is recalled, however, that the aponeuroses of the transverse muscles are quite thin (about a line in thickness), it becomes evident that the cicatricial union of these edges when merely brought in apposition will be weaker than were the aponeuroses before their division. Impressed by the fact, or what I believe to be a fact, since 1897 it has been my

[1] Read before the Pennsylvania State Medical Society, September 28, 1904.

practice to overlap the fasciæ from one-third to one-half inch as a routine method, and the results secured in the prevention of hernia have been such as to convince me that this method of closing the abdominal wall insures a firmer union and a more certain safeguard against the development of hernia than any other method in use. Since 1897 there have been approximately eleven hundred and fifty wounds in the abdominal wall closed by this method, and of this

Fig. 1.



Closing the Abdominal Wound.

number only three cases of hernia are known to have occurred. There has been no case of hernia among the Alexander operations. The method has been used in the closure of the ordinary incisions of the abdominal wall, for the closure of incisions of the inguinal canal when opened to shorten the round ligaments, in all operations for the cure of hernia, whether umbilical, inguinal of ventral (postoperative), and for the cure of diastasis of the recti muscles, demonstrating what I have previously claimed for it ("A New Method of Suturing the Abdominal wall in Celiotomy," *Amer. Jour. Obst.*, 1897, vol. xxxv, No. 4; "Shall Absorbable or Non-absorbable Ligatures and Sutures be employed in Hysterectomy and Salpingo-oophorectomy?" Medical News, October 15, 1898; "Alexander's Operation," *Amer. Gynæc. and Obst. Jour.*, May, 1899; "Remarks on the Influence of Technic upon the Results of Closure of Wounds of the Abdominal Wall," *Boston Med. and Surg. Jour.*, March 8, 1900), that it is of universal application.

I have in preparation a historical paper dealing with the development of the method, showing how different surgeons have used the principle in particular operations, more especially for the cure of inguinal hernia. It is not my intention to dwell upon this phase of the subject at this time, but merely to insist upon the general applicability of the principle, and upon its value in the closure of all wounds of the abdominal wall.

In practice the use of the method is quite simple. The incision in the hypogastrium for operation on the female pelvic organs may be taken as the type. This incision is made by choice through the inner border of the right rectus muscle. In closing the wound, the peritoneum is first closed with a continuous suture of fine cumol catgut. The fat is then dissected from the upper surface of the aponeurosis of the transverse muscles on the left side of the wound from one-third to one-half inch. The aponeurosis upon the right side of the wound is then separated for an equal distance from the rectus mus-

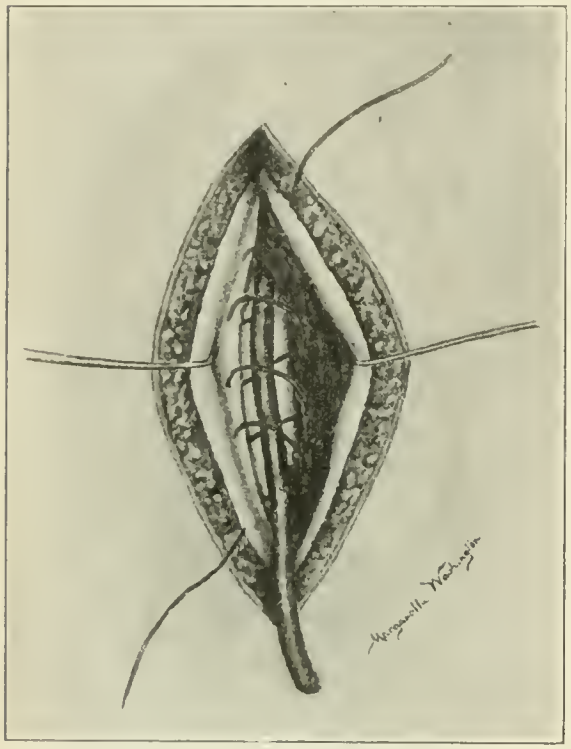
Closure of the wound in the aponeurosis of the oblique muscles. Overlapping the aponeurosis by superimposing that of the right side of the wound upon that of the left, and suturing with a continuous chromicized catgut suture.

cle. The muscles and fasciæ are then sutured by means of a medium weight chromicized catgut suture in the following manner: The suturing is begun at the lower angle of the wound upon the left side. The suture is passed from above downward through the aponeurosis and rectus muscle. Then the separated bundles of the rectus muscle are united with a continuous suture until the upper angle of the wound is

reached, when the suture is passed from below upward through the aponeurosis upon the left side of the wound. The suture is then passed from below upward through the aponeurosis upon the right side of the wound, and an additional suture is taken above this point to fix the suture and take the strain off that part which has brought the muscle in apposition. The aponeurosis is then closed from above downward by catching the aponeurosis upon the left side of the

Fig. 3.



Shortening the Round Ligaments.
Suturing the internal oblique round ligament and Poupart's ligament with chromicized catgut—to fasten the ligament and obliterate the canal.

wound after the manner of the Lembert intestinal suture, and then passing the needle from below upward through the aponeurosis upon the right side of the wound. When this suture is drawn taut, it slides the aponeurosis of the right side of the wound upon that of the left side and holds the two in apposition; the amount of overlapping depending upon the distance from the edge at which the needle is passed through the aponeurosis upon the left side of the wound. The process is repeated until the lower angle is reached, when the two ends of the suture are tied. In long wounds two or more mattress sutures are placed to take tension off the lines of continuous suture. The fat is closed with a continuous suture of fine cumol catgut. The skin is closed with fine cumol catgut suture by the intracuticular method. When median wounds are long, extending near or above the umbilicus, care is taken to unite the posterior aponeurotic sheath of the rectus muscle with the peritoneum. For this purpose frequently a fine chromicized catgut suture is used. This principle is followed also in wounds through the upper portion of the rectus muscle and in wounds of the rectus muscle in operating for appendicitis, in order to secure firm union of the posterior sheath of the rectus.

In operations in the groin, whether for shortening the round ligaments or for the radical cure of inguinal hernia, the internal oblique muscle and any convenient aponeurotic tissue is sutured to Poupart's ligament with chromicized catgut, care being taken to begin the line of suture at or above the upper border of the internal ring. The incision in the aponeurosis of the external oblique

Fig. 4.

Overlapping the aponeurosis of the external oblique in closing the inguinal canal.

is then closed by overlapping the aponeurosis to the outer side of the wound upon that to the inner side of the wound.

University of Pennsylvania.—Mrs. Samuel Dickson has donated $25,000 to the University, half to be devoted to the University Christian Association, the other half to the children's orthopedic ward in the hospital. The new gymnasium of the University was dedicated, December 14, in the presence of numerous alumni and guests. It is said to be the finest of its kind in the country, the cost when completed being $1,000,000. A system of compulsory physical exercise has been instituted under the direction of Dr. R. Tait McKenzie.

THE ASSOCIATION OF CANCER AND TUBERCULOSIS.

BY W. A. BASTEDO, PH.G., M.D.
OF NEW YORK.

Like some other dogmas of medical science, it has long been taught that cancer and tuberculosis are mutually antagonistic. Sidney Martin recalls seeing only two cases of the association, and the Fenwicks write: "Most authorities are agreed that the two complaints rarely coexist in the active state." In a fair-sized audience of medical men, McCaskey was unable to find one who had seen the association. On the other hand, Moak maintains that there is no antagonism, and Claude, who made an extensive study of the subject, concluded that either might be favorable to the development of the other.

We had two of these cases at St. Luke's Hospital, New York, and I have to thank Drs. C. F. Collins, Egbert LeFevre and F. C. Wood for permission to use the case histories and post-mortem records. In the subsequent review of reported cases, only those are considered which have been verified histologically or about the correctness of which there seems no reasonable doubt. Many of the older cases have been omitted, as for example, that of Annan of pulmonary phthisis, with carcinomatous ulcers in the bowel; in the absence of histological examination these ulcers may have been tuberculous. A case of Kidd's with tumor of the lung and cavity formation has been claimed as an example of mutual tolerance, though Kidd expressly states that the lung showed no tubercle tissue and no tubercle bacilli. Our cases were:

Case I.—D., male, aged forty years, married, boxmaker, entered hospital November 12, 1899, and died three months later. Family history uncertain. Ten months before admission began to cough, had pain in anterior chest and night-sweats. Since then has had several fair-sized hemoptyses. On admission the physical signs were those of miliary tuberculosis of both lungs, and tubercle bacilli were found in the sputum. On December 26, he complained of pain in back and left mammary region, and a tender prominence was noted over fourth spinous process. It was taken for a kyphos, the mammary pain being attributed to pressure on the nerves, but no pain was elicited on jarring the body or on crowding down the ribs. On January 12, leucocytes 18,200. On February 13 a tumor 5 x 5 cm., rounded elastic in center and hard at periphery, was felt on the liver surface immediately below the ensiform process; to the right of this were felt a few small nodules. He died two days later. The temperature on admission was of the steeple variety, ranging from 98.4° to 103.2° F. The excursion gradually became less, and from December 26, the day on which the lump on the back was first noticed, until he died, fifty days later, the temperature rose above 100 only seven times, and was practially the same in the morning as in the afternoon.

Post mortem.—Right lung.—Dense adhesions, middle and lower lobes completely converted into a large cavity which is nearly filled with thin pus. At the hilus of the lung is a tumor about the size of a lemon, and included in its mass are swollen and pigmented lymphnodes. *Liver.*—On anterior surface left lobe is a large cancer, hard externally and soft in the center; scattered through the liver substance are a number of smaller tumors. *Pancreas.*—In the head is a neoplasm of 2 cm. diameter; midway between head and tail are two smaller nodules. *Stomach.*—One small nodule beneath mucous membrane. Spleen, both kidneys and left suprarenal show metastatic nodules, and there are many such along the whole vertebral column and under the costal pleura along the ribs. There is one large nodule surrounding the fourth spinous process. Intestine and brain normal. The histological report is not accessible.

Case II.—H., male, aged thirty-nine years, mining engineer, born in Sweden, has traveled much in Africa and South America. Entered November 2, 1899, and died two years later. Father died of inflammation of the lungs; no other family history obtained. Patient had had pneumonia, yellow fever, bilious intermittent fever, and several attacks of hemorrhagic malarial fever with bloody urine and stools. Eight months ago he noticed loss of flesh and strength, cough, blood-streaked expectoration and occasional night-sweats. At the Presbyterian Hospital tubercle bacilli were found, and they were also present when he entered St. Luke's, but though often sought, they were not again found during his first stay of eight months in the hospital. His lesion seemed quiescent, the physical signs being those of emphysema and fibrosis in the right lung, with chronic bronchitis and adherent pleura of both sides. The abdominal veins to the right of the umbilicus were notably enlarged; spleen and liver not felt. He had frequent asthmatic attacks. During this stay of eight months he had frequent hemorrhages from the bowels with diarrhea. The blood was mostly dark, and sometimes continued to show itself in the stools for a week or more, the patient becoming very feeble and anemic. Some stools were pure blood. Preceding the hemorrhage there was much pain in the liver region, but it seemed to vanish on the appearance of the blood. He occasionally had cramps in the abdomen, and for one period of several days had either a chill or chilly feeling each day. The blood showed no plasmodium nor noteworthy changes in size or shape of the red cells. Rectal examination was negative though later he developed hemorrhoids. A species of *Anguillula* was found in the mucus which coated his stool when formed, but we were unable to determine whether it was true *Anguillula stercoralis* or one of the numerous species from our ordinary fresh-water streams.

In July, 1900, he left the hospital, weighing 154 pounds and having lost 19 pounds in eight

months. His cough was slight, there was no sputum, and his loss in weight was attributed to his frequent hemorrhages. These were supposed to be due to cirrhotic liver. A year later, September 12, 1901, he returned weighing 120 pounds, and five weeks later died. On admission there were marked signs of tuberculosis in both lungs and many tubercle bacilli in the sputum. Liver and spleen not felt. On October 3, liver just palpable, spleen negative. On October 15, the blunt edge of the liver was felt in the median line two inches above the umbilicus; just to right of midline was a horizontal, hard, ridge-like, oval, tender lump. Spleen negative. He died two days later. From admission until death, five weeks, he had frequent shaking chills and abdominal pain. The diazo test of the urine was repeatedly negative, but on October 10 reacted weakly and on October 17, the day of death, was clearly positive. The blood on October 4 showed 3,392,000 red cells, 45 per cent. of hemoglobin, and of the leucocytes 85 per cent. were polymorphonuclear.

It is noteworthy that, although he had repeated chills and rapid respiration with cough and profuse expectoration, his temperature after October 2, the day before his liver was first felt, never rose above 99° F., and tended to be subnormal. Twice it reached 94°, three times 95°, and once 96° F.

Post-mortem.—Right lung—Dense pleuritic adhesions, two cavities, diffuse consolidation with areas of cheesy degeneration and miliary tubercles throughout. *Left lung*—Pleuritic adhesions, one small antrum and scattered miliary tubercles. *Liver*—Near anterior border right lobe was rounded eminence, 15 x 10 x 6 cm., which on section is a new growth broken down in center and containing clear viscid fluid. Several small tumors are scattered through the enlarged liver. Near the head of the pancreas is a large, very hard lymph-node. There is chronic colitis, and in the region of the sigmoid flexure are many small ulcers about 1 cm. or less in diameter, and some old ulcer cicatrices.

Histological examination.—Lungs—Tuberculous tissue with giant-cells, large areas of cheesy degeneration, some of which are wholly encapsulated; much connective tissue. *Liver*—Infiltration of lobules with carcinoma cells, considerable stroma between lobules. The ducts and blood-vessels are surrounded by cancer cells. The lymph-node from near pancreas is cancerous.

This then would seem to be a case of pulmonary tuberculosis with chronic ulcerative colitis and cancerous cirrhotic liver. It may be that the liver pain and hemorrhages two years before death were due to a simple cirrhosis, or the cancer may have already begun to involve the liver and hepatic vessels. Might not the cancer have developed in a liver already cirrhotic, as it sometimes does in other sclerosed or cicatrized tissues?

Both these cases had extensive tuberculous involvement of the lungs with cavity formation, yet for some time preceding death the temperature was nearly normal and not at all septic or tuberculous, and the patients seemed to die as from cancer rather than from tuberculosis.

Of the reported cases of association where *the two processes were active but did not involve the same tissue* the tuberculosis was mostly in the lungs, intestine and lymph-nodes. Rarer were Pott's disease, tuberculous pericarditis, tuberculous meningitis, fistula in ano and tuberculous knee. The site of the cancer was: *Breast* 10 times (Cases of Majer, Clement and Williams 8 cases; *uterus* 10 times (Briggs, Middlesex Hospital, Oppolzer, Williams 7 cases); *cheek* once (Middlesex Hospital); *lower jaw* once (Clement); *upper jaw* once (Middlesex Hospital); *tongue* once (Middlesex Hospital); *pharynx* once (Meunier); *larynx* once (Middlesex Hospital); *œsophagus* 13 times (Béhier and Gallard, Middlesex Hospital, Parmentier, Peter, and Porcharies 9 cases); *stomach* 39 times (Béhier, 5 of Boas, Clement, 2 of Fenwick, Gouin, Kollick, 2 of Metterhausen, Middlesex Hospital, Moutard-Martin, 12 of Mouisset, Osler and McCrae, Pauli, Peter, Pierazzini, 8 of Schräder); *liver* 8 times (Béhier, Fenwick, McCaskey, 3 of Mouisset, Picot, Pierazzini, our case No. 1); *pancreas* 3 times (Fenwick, McCaskey, our case No. 2); *intestine* 4 times (Fontoynont, Forster, Lubarsch, Metterhausen).

Pauli had a case of gastric cancer with tuberculous pericarditis. Metterhausen had one of pyloric cancer with tuberculosis of the neighboring lymph-nodes; and one of pyloric cancer with miliary tuberculosis of the liver and mesenteric lymph-nodes. Clement had three cases, (1) cancer of lower jaw with tuberculous cervical lymph-nodes, (2) cancer of right breast with tuberculosis of right axillary lymph-nodes, (3) cancer of stomach, with tuberculosis of liver, lymph-nodes of the gastrohepatic omentum, and axillary lymph-nodes; no trace of cancer was found in any of these lymph-nodes. The Fenwicks relate a case of hemoptysis, recent pleurisy and extensive tuberculosis of right lung, with latent carcinoma of the posterior wall of the stomach and metastases in the liver and the lymph-nodes above the pancreas. Meunier's case died from a tuberculous bronchopneumonia following gastrotomy for inoperable pharyngeal epithelioma. In Béhier and Gallard's case, an œsophago-pulmonary communication was formed by ulceration of an œsophageal cancer on the one side and the softening of tubercle on the other. Lubarsch had a caseous peribronchitis with six cancerous nodules in the ileum (verified histologically). Fontoynont had a case of tuberculosis caries of the spine with cylindrical epithelioma of the transverse colon. Forster reports pulmonary tuberculosis with cancer of colon, and Porchaire cancer of œsophagus with tuberculosis of testicle. Of Williams 130 clinical cases of breast cancer, five had phthisis, two fistula in ano, and one lupus vulgaris. Of his 130 uterine cancers

five had phthisis, one fistula in ano, and one a tuberculous knee. In all these cases the tuberculous lesions were active and existed independently of the carcinomatous.

But there are a number of cases where *both affections attack the same tissue or organ, i.e.,* presumably either process attacks a tissue or organ in which the other has already gained a foothold. Among the cases in which the tuberculosis is the antecedent lesion, the most familiar are those of lupus vulgaris upon which epithelioma ta have developed. Fordyce writes: "Carcinomata develop from active lupus or from its scar-tissue so frequently as to indicate more than an accidental relationship." Garres described a lupus of the larynx in which, aside from pronounced tuberculosis, he noted epithelial proliferation into the submucosa, and epithelial pearls. Beausoleil had a similar laryngeal case. In 118 cases of lupus vulgaris, DuBois-Havenith found five epitheliomata. Desbonnets was able to find 90 reported cases of the double lesion, and writes "It does not differ from epithelioma on ordinary skin." Ashihara, however, claims that it does differ from ordinary skin cancer, as it occurs at a comparatively early age, advances rapidly, rarely forms metastases, and often recurs after removal. Anderson writes in Allbutt's System: "It is especially malignant and may show itself at an unusually early age." Of Steinhauser's 83 cases, 24 per cent. were under forty years of age. On the other hand, Desbonnets claims that when the epithelioma appears the lupus has existed on the average thirty years before the epithelioma developed: Hallopeau and Leredde say forty years. C. W. Allen showed a case in which a lupus of twenty-four years had in six months developed an epithelioma involving half the forehead. Stelwagon speaks of a long-standing lupus which became epitheliomatous and ran a rapid and malignant course. The opinion among dermatologists is, therefore, that *lupus* is in some way *favorable to the development of epithelioma.*

According to Ziegler, "in lupus tissues the epithelial cells are in part subjected to altered conditions of nutrition, and in part are displaced, so that they are often lodged among the deeper layers of the tissues." He attributed the epithelial proliferation to ulceration and the formation of cicatrices. In Tillmann's Surgery we find "in lupus the epithelium often grows into the subcutaneous cellular tissue in the form of irregular epithelial proliferation. This explains the fact, perhaps, that persons afflicted with lupus not infrequently develop epithelioma." Crouzon notes that in lupus there exist various benign new growths of irritative origin. Hallopeau and Leredde say, "In old lupus, treated, sclerosed, cicatrized, there tend to form epithelial inclusions." Much more has been written on the subject than we have indicated, and the concurrence of opinion is, that lupus tissue is subject to abnormal epithelial proliferation.

Does the epithelioma merely develop as in scar-tissue, or is the tuberculosis an important factor? Fordyce says: "Growths may arise in indifferent scar-tissue but in lupus the course is more rapid." Leloir believes that a cicatrix is necessary. Lang, Raymond, Mibelli think scar-tissue unnecessary. Bidault suggests an origin in the sebaceous glands. Claude finds that cancer may develop in a cicatrized or in an active lupus, but that even in this latter there may be cicatricial areas. Crouzon says, "It may develop on an ulcerated lupus, but is more frequent where not ulcerated." According to Anderson, "In most cases the cancer first attacks the spreading edge of the lupus, but in a considerable number it originates in the cicatrix." Desbonnets found the development in the cicatricial area only 21 times in 90 cases. Fordyce writes: "In lupus there is nearly always active tuberculous disease, and thus less resistance offered to the epithelial growth," and again: "In lupus a constant irritation is exerted on the epithelial layer, which causes it to undergo hypertrophy, and ultimately may lead to its becoming the seat of a malignant growth."

Cancer certainly has a tendency to develop at the site of any long-standing irritation, as in epithelioma of lip, cancer arising from ulcer of the stomach, and cancer of the uterus in old laceration of the cervix.

It seems certain, then, that scar-tissue and irritative lesions are distinct factors in the production of epithelioma, and it is probable that the combination of scar-tissue with tuberculous disease makes a double preparation for the neoplastic growth, the tuberculous process being both an irritative lesion and one that tends to enfeeble the resistance. Other similar chronic inflammatory conditions of the skin do not rank with lupus in epitheliomatous transformation, for in syphilis there are comparatively few reported cases, and in lupus erythematosus we could find only four cases in the literature. It may be that the very long course and repeated cicatrizations of lupus vulgaris place it in a class by itself, for certainly syphilitic lesions do not persist thirty or forty years. It is well to note also that Roger Williams and also the Fenwicks mention the rarity of a syphilitic history in those patients suffering with cancer.

Of cases other than lupus in which tuberculosis and cancer involve the same tissue or organ, we shall only here and there attempt to indicate which is the prior lesion. The following are the reported cases: Involving the breast 7, uterus 1, larynx 2, lungs 20, esophagus 4, stomach 3, small intestine 3, large intestine 4, rectum 3, liver 1; also 2 cases of cancer only of the breast with the double lesion in the axillary lymphnodes, and Ribbert's eleven cases in which he failed to find tubercle bacilli, and made his diagnosis mainly on the presence of giant-cells. These cases were: 6 of lip, 1 each of mouth, tongue, gum, eyelid and penis; he claims to have excluded syphilis, leprosy, actinomyces, animal

parasites and foreign bodies as the cause of the giant-cells.[1]

Of special interest among these cases might be mentioned: Haug's case of tuberculous nodules on the lobe of the ear, among which epithelioma developed; Moak's five cases: one, the primary cancer in the prostate, and the tuberculosis in the lungs, and there were metastatic combinations of the two lesions in lungs, bronchial lymph-nodes, adrenal, liver and spleen; two, adenocarcinoma of sigmoid flexure, in which a tuberculous process was working its way between the intestinal wall and the fungoid edge of the neoplasm undermining the latter; the interior of the cancer alveoli were necrotic and cheesy and contained tubercle bacilli; there was combined metastasis in liver and kidney; three, recurrent carcinoma with tuberculosis, apparently primary, of the mammary gland, with the combined lesion also in the axilla; four and five, both cases of uncomplicated cancer of the breast with the double lesion in the axillary lymph-nodes. Crawford observed a scirrhous cancer in a chronic interstitial mastitis, which on account of caseating areas was supposed to be tuberculous, though neither giant-cells nor tubercle bacilli were found; in the axilla were a large caseating mass of tuberculous lymph-nodes, two single cancerous lymph-nodes, and between axilla and breast some lymph-nodes with tuberculosis and cancer side by side. Warthin found the combined lesion in the breast in two instances; in one of the cases the axillary lymph-nodes were examined and showed the double lesion. Kallenberger reports a woman who had pulmonary tuberculosis; the breast became inflamed and was found to contain tuberculous tissue surrounding, but sharply delimited, from, nests of cancer cells. Pilliet and Piatot briefly record a carcinoma of the breast in which was a fistula 6 cm. long; section showed both tuberculosis and cancer. From the larynx (vocal cord) Zenker removed an epithelioma, in the center and edges of which were tuberculous foci containing a few tubercle bacilli. Crone and Baumgarten extirpated the larynx for recurrent epithelioma, and cancer and tuberculosis were found intimately associated in this and in some large neck glands adjacent to a cutaneous cancer metastasis.

In the lungs, Friedländer, Menétrier, Schwalbe, and Wolf (2 cases) found cancer arising from the wall of a tuberculous cavity. All were flat-celled epitheliomata seated on sclerotic tissue, and supposedly arising from the alveolar epithelium. In studying primary cancer of the lung, Wolf observed the association in 13 cases, among which worthy of note are: One case with miliary carcinosis intermingled with miliary tuberculosis, one case with miliary carcinosis and a tuberculosis which was not miliary, and two cases of cancer in a tuberculous cavity. Lubarsch reports two cases, a primary lung cancer in pulmonary tuberculosis and metastatic cancer in fresh areas of tuberculous infiltration in the lung. Barth observed a tuberculous bronchopneumonia in a part of the lung whose main bronchus was obliterated by a primary cancer. Olmer reports tuberculosis of both lungs, liver and spleen, and in one lung a neoplasm which was either a tubular epithelial cancer or an alveolar sarcoma.

In the esophagus, Zenker discovered an epithelioma, the stroma of which and the adjacent esophageal tissue were tuberculous and showed tubercle bacilli. Cordua also reports a cancer of the esophagus invaded by Koch's bacillus. Pepper and Edsall had a case of tuberculous occlusion of the esophagus with partial cancerous infiltration. Weyeneth found cancer of the esophagus invaded by tuberculosis in a case with tuberculous cavities in the lungs. Béthier and Gallard's esophago-pulmonary fistula (see above) might also be mentioned here.

In the alimentary tract, Claude had a case with tuberculosis in lungs and large intestine, and a tumor of the stomach, of which about one-third had ulcerated away. The tumor was adenomatous in some parts and carcinomatous in others. Dense and caseating tubercle tissue had cut off the tumor's nutrition, with resulting necrosis, but nowhere did the tubercle tissue invade the substance of the cancer, though in immediate contact with the cancer cells. There were tubercle bacilli, giant-cells, and round-cell infiltration. According to Claude, "this was a tuberculous infection engrafted on a growing epithelioma and causing its partial destruction, the cancer having arisen from polypoid adenomata." Friedländer found tubercle tissue in a gastric cancer which had developed on the cicatrix of a simple ulcer. Lubarsch had a case with tuberculosis of lungs and mesenteric lymph-nodes, and tuberculous ulcers of trachea, ileum, ascending colon and rectum—with a carcinoma of the ileum producing stenosis. (The case of Jackson, 1848, involving the testicle, is not verified.)

From these cases it is evident that *not only may cancer and tuberculosis attack the same person*, but that *their lesions may lie side by side, or may intermingle, or that the one may develop in a tissue already the stronghold of the other.* Tuberculosis implies chronic inflammation and enfeebling of tissue-resistance; but that the malnutrition of tuberculosis favors cancerous growth cannot be postulated, for cancers develop in those of good nutrition as well as in the emaciated. On the other hand cancer may, by its effect on nutrition, favor tuberculous infection, or by changing the character of the epithelium, or by ulceration, may permit the entrance of the tuberculous germs. Or tuberculosis may develop in the neighborhood of a can-

[1] These cases were reported as follows: *Breast*—Crawford, Kallenberger, Koster, Moak, Pilliet and Piatot, Warthin (2); *Ear*—von Franque; *Larynx*—Crone and Baumgarten, Zenker; *Lungs*—Barth, Dittrich, Friedländer, Friedreich, Lubarsch (2), Menetrier, Olmer, Schwalbe, Wolf (2); *Esophagus*—Bethier and Gallard, Cordua, Pepper and Edsall, Weyeneth, Zenker; *Stomach*—Claude, Friedländer, Loewenstein; *Small Intestine*—Lubarsch, Naegeli, Weyeneth; *Colon*—Dalton, Metterhausen, Moak, Naegeli; *Rectum*—Baumgarten, Manjkowski, Naegeli; *Liver*—Dittrichs; *Lobe of Ear*—Haug. *Axillary Lymph Nodes*—Crawford, Moak (2).

cer, the resistance of the tissue being lowered by the influence of the neoplasm in the vicinity; or a latent tuberculosis in a lymph-node may become active when a cancer arises near by. The cancer may also act mechanically, as when it obstructs a bronchus or vessel, and tuberculosis appears in the stagnated and congested area thus produced.

Cancer and tuberculosis are certainly not antagonistic. Indeed they might more often involve the same structure, were it not that, as suggested by Rokitansky, 1838, the parts usually attacked by cancer are not those frequently invaded by tuberculosis. Williams, in 7,297 cases of primary cancer, found 80 per cent. located in superior maxilla, lower lip, mouth, tongue, esophagus, stomach, uterus, prostate, bladder, external genitals and breast, regions where tuberculosis is not common. In Reiche's 11,930 cancer cases the site of the neoplasm in 79 per cent. was esophagus, stomach, rectum, liver, gall-bladder, pancreas, bladder, uterus and breast. On the other hand, tuberculosis attacks mostly the lungs, serous membranes and small intestines, which are seldom the seat of cancer.

Aside from their occurrence in the same tissue we might also expect the two lesions in the same person more commonly, were it not that, as shown by Cruveilhier, 1828, the period of life for the greatest tuberculous activity is that at which cancer is comparatively rare, while active tuberculosis is less common at the later period of life, when cancer is in the ascendency. Muirhead states that in Great Britain the average age at death from cancer is about sixty years. Of 11,930 deaths from cancer Reiche found that 73.44 per cent. took place after fifty. On the other hand, of 10,649 deaths from pulmonary tuberculosis, Barié ascertained that only 17.8 per cent. occurred after fifty, and in 92,141 deaths at the age of sixty or over, only 2.3 per cent. were due to tuberculosis. Of Bariés 10,649 deaths from pulmonary tuberculosis, the semi-decades in which ten per cent. or more of the deaths took place were those between the ages of twenty and forty-five years, so these years may be taken as the most common ones for death by tuberculosis; at this period of life only 16.14 per cent. of all the deaths from cancer occurred. The semi-decades in which ten per cent. or more of Reiche's 11,930 deaths from cancer took place were those from the ages forty-five to seventy-five years, so these may be taken as the common ones for cancer; at this period of life 26.6 per cent. of the tuberculous deaths occurred. It is interesting, too, to note that the highest number of tuberculous deaths in any semi-decade occurred at the ages thirty to thirty-four, viz., 15 per cent., and during this period only 2.36 per cent. of the cancer deaths took place; also that the highest number of cancer deaths, 14.2 per cent., occurred at the ages sixty-one to sixty-five, and at these ages only 3.35 per cent. of the deaths from tuberculosis took place. The failure of the two lesions to be more frequently associated may, therefore, be largely accounted for in this way.

Tuberculosis, presumably, is fatal to large numbers in early life who might, had they lived longer, have developed cancer. It is evident, too, that if in early life tuberculosis develops and is conquered, a healed or latent process will be found at autopsy. We naturally, therefore, expect to find healed tuberculosis more frequently at autopsies on older people than at autopsies on the young. In Reiche's 11,930 cancer cases, the greatest proportion of cancer deaths to all deaths at any given age of life was 7.3 per cent., while in 1,196 post-mortems in which healed tuberculosis lesions were found (Fowler, Heitler, Lubarsch, Martin, Zahn) 20.4 per cent. had cancer. Thus the prevalence of cancer is less in the community in general, even at the cancer age, than in those with healed tuberculosis. Such facts have led Fowler and Godlee to say, "It is remarkable that the tissues of an individual who ultimately succumbs to a disease of the type of cancer should have had at one time resisting power sufficient to overcome an established tuberculosis."

The following statistics may be of interest: In 14,415 post-mortems following death from all causes (Dürck, Lubarsch, Osler, Zahn) tuberculosis active or healed was found in 35.5 per cent. In 1,955 post-mortems for cancer (Boas, Lebert, Loeb, Lubarsch, Osler and McCrae, Rapok, Sandor-Miclesco, Schräder, Williams) only 15.3 per cent. showed tuberculosis, active or healed. In 1,014 post-mortems for cancer (Boas, Kelynack, Lebert, Lubarsch, Mouisset, Osler and McCrae, Williams) active tuberculosis was found in 5.5 per cent., and in 672 post-mortems for cancer (Boas, Lubarsch, Osler and McCrae, Williams) healed tuberculosis was found in 10.87 per cent. The tuberculosis post-mortems of course include many cases of young age, when cancer would be very rare.

Clinically, in 260 cases of breast and uterine cancer, Williams found 5.8 per cent. of active tuberculosis; and in 75 women with non-cancerous tumors, he found 5.3 per cent of active tuberculosis. From these statistics it would seem that active tuberculosis occurs in about 5½ per cent. of all cases that die of cancer, about the normal frequency for active tuberculosis in all persons at the cancer age. But to draw any positive conclusions from post-mortem statistics it would be necessary to compare the percentage of cancer cases in the tuberculous at any given age with the occurrence of cancer in the non-tuberculous at the same age. Unfortunately, autopsy statistics of cases in which both diseases occur fail to state the ages of the subjects. From our study of cases so far, however, we may infer, we believe, that in all probability the two diseases neither antagonize nor favor each other in any specific manner. It seems probable that tuberculosis does not favor the development of cancer any less or any more than other long-standing lesions involving chronic irritation or de-

pressed vitality of the tissues: and that cancer does not favor the development of tuberculosis any less or any more than other conditions which markedly influence nutrition and tissue-vitality.

The following cases of antagonism are too few to influence our conclusions. In our two cases the death was rather from cancer than from tuberculosis, and when the cancer became active, the regular tuberculosis temperature subsided. Picot remarks of a case of pulmonary tuberculosis with cancer of the liver "From day to day the patient became worse, in spite of the *absence of fever.*" In McCaskey's case there was not at any time either fever or accelerated pulse.

The Fenwicks write, "In one case which we were able to watch through its course, a rapid tuberculosis of the lungs and intestine came suddenly to a halt when symptoms of malignant disease of stomach and pancreas made their appearance. After death, at the end of eight months, not only was the pulmonary lesion found completely quiescent, but more than thirty ulcers in the bowel had either partly or completely cicatrized."

The recession of cancer on the outbreak of pulmonary tuberculosis is reported by Paget; and Sigg describes the dwindling of a recurrent carcinoma of breast and axilla as soon as active pulmonary tuberculosis made its appearance. In view of the fact that so many cases of association are found in the literature, these very few cases of apparent antagonism must not be given undue weight, though certainly lending support to Martin's remark that cancer does not antagonize the first infection of tuberculosis, but tends to retard its progress.

The statement sometimes made that cancer occurs at an earlier age in those with tuberculosis is not borne out by Osler's statistics of pulmonary tuberculosis; in our discussion above of lupus we have noted opposing opinions in this regard.

Heredity.—Besides the cases of actual association, the seeming hereditary relation between the two diseases is of interest. Burdel, citing a case in which the mother had cancer, and the patient, a sister and two children had tuberculosis, states that "tuberculosis of the child appears to be favored by cancer of the parents." Schley's patient, with primary tuberculosis of the breast, had a sister with cancer of the uterus. The Fenwicks say "Of our gastric cancer cases 26 per cent. possessed one or more near relations who had succumbed to phthisis . . . It is also interesting to observe that the progenitors of cancerous families are often themselves the sole survivors of tuberculous families; and that, while the cancerous proclivity shows itself most in the elder children, the younger ones not infrequently succumb to tuberculosis. In other instances cancer and tuberculosis alternate in successive generations." Williams writes "Pulmonary tuberculosis is by far the most prevalent disease among the relatives of cancerous persons, who are very much more prone to it than the rest of the community. . . . Indeed the liability (of the offspring of the cancerous) to pulmonary tuberculosis is so considerable as to even equal that of the (offspring of the) tuberculous themselves. . . . Hence those who survive the peculiar kind of degeneracy associated with the tuberculous predisposition are at a later period of life especially prone to cancer." Williams found a family history of tuberculosis in 10 to 25 per cent. of the general community, while in his 260 cases of uterine and breast cancer he obtained a family history of tuberculosis in 50 per cent. From various statistics which we have gathered, we find a family history of tuberculosis in the tuberculous in 48 to 60 per cent., a family history of tuberculosis in the cancerous in 25 to 50 per cent., and a family history of tuberculosis in the general community in only 10 to 28 per cent. We have been unable to obtain adequate statistics in regard to a family history of cancer in the tuberculous. In Osler and McCrae's 150 cases of cancer of the stomach at Johns Hopkins Hospital, 25.3 per cent. gave a family history of tuberculosis, exactly the same proportion as in 150 control non-cancerous cases chosen at random.

Before concluding I should like to refer especially, as of clinical importance, to those cases in which tuberculous lymph-nodes have been found in the neighborhood of a cancer. Metterhausen had two cases of pyloric cancer with tuberculosis of the neighboring glands. Clement had three cases: cancer of lower jaw with tuberculous cervical glands, cancer of right breast with tuberculosis of the right axillary glands, and cancer of the stomach with tuberculosis of the omental and axillary glands. Hildebrand recalls cases of amputation of the breast for carcinoma with tuberculous axillary glands, and of cancer of the lip with tuberculous glands in the neck. The Fenwicks write, "Not a few examples of malignant disease of the stomach present old tuberculous lesions in the glands of the left supraclavicular fossa."

Our conclusions may be stated as follows:

1. Cancer and tuberculosis not infrequently occur together in an active state, and may be intimately associated in the same tissue.

2. There is probably neither specific favoritism nor specific antagonism between the two types of disease.

3. There are a few reported cases in which one of the affections seems to have exerted a modifying influence on the course of the other.

4. Lupus favors the development of epithelioma.

5. Cancer is more common among those with latent tuberculosis than among others at the cancer period of life.

6. The common age for cancer is not the common age for active tuberculosis (Cruveilhier, 1828).

7. The common sites of cancerous involve-

ment are mostly not those of tuberculous involvement and vice versa (Rokitansky, 1838).

8. A family history of tuberculosis is more frequent in the cancerous than in the general community, and there may be some hereditary relation between the two.

9. A latent tuberculous process in a lymph-node may become active when a cancer develops in the neighborhood.

10. Lymph-node enlargement in the vicinity of a cancer is not always cancerous (Claude, 1899), and may be solely tuberculous.

THE MININ RAY.

BY WILLIAM GRAY SCHAUFFLER, A.M., M.D.,
OF LAKEWOOD, N. J.

THE recent death of Niels Finsen has removed from scientific medicine one to whom we owe a great debt. It is given to but very few in each generation to accomplish as much good for mankind as did this noble and modest worker in photo- and electrotherapy.

All the more does it become the duty of each individual to add his contribution, however humble, to the scanty knowledge we at present possess of the therapeutic value of light and electricity.

It has been my fortune for the past two years to have done considerable work with the so-called Minin ray, as brought to this country and put on the market by a western house. The apparatus consists of a series of incandescent lamps of about 16, 32 and 50 candle-power, together with suitable reflectors, cords and stand. The glass bulbs are made of a peculiar, very dark blue glass, and the light transmitted apparently has lost much of its original heat, as experiments have demonstrated. That the transmitted rays are not ultra-violet, as some claim, is proved by the fact that Willemite does not fluoresce when exposed to them. Just what rays do pass through this blue glass, remains to be shown by further experiment, but the results obtained are so varied and striking that I have collected a number of cases from my own practice, in the hope that others may be induced to try the Minin ray with the same gratifying results to themselves and their patients.

Discarding the stand furnished with the lamps, I attach the same by means of a six-foot cord to any 110-volt lighting current, either direct or alternating, allowing the patient or nurse to hold the reflector six to eight inches from the part to be "rayed." The only caution needed is not to allow the glass bulb to touch the skin. The bulb heats so quickly and retains the heat to such an extent that a blister would immediately follow contact with the skin. Burns of the skin from long-continued use of the rays have not resulted in my experience, although a marked reddening of the surface rayed is immediately apparent.

The application of the light lasts from ten to twenty minutes, according to the part to be acted upon and the result sought. In no case have I found any unpleasant reaction resulting from the use of the Minin rays, and in almost all cases there have been positive favorable results.

Case I. Old Suppurating Burn.—J. C., forty-five years old, laborer. Had burn of second degree, covering whole back of right hand and fingers. When first seen it had been neglected, and was suppurating and covered with filthy crusts. Patient had not slept for two nights. Cleaned with an antiseptic and Minin ray applied for fifteen minutes. Pain was relieved at once. Dry dressing applied. On following two days

same treatment was applied, and on fifth day the wound was healed. Following the first treatment patient was free from pain. No contraction of skin or muscle resulted.

Case II.—F. C., Twelve years old. While he was setting off fireworks a bomb exploded prematurely in patient's face, burning him from chin to hair and from ear to ear. When first seen, within half hour after the explosion, the patient was screaming with pain. His face was blackened and swollen, his eyes closed and his eyebrows, eyelashes and hair over forehead burned to a crisp.

The face was rayed for thirty minutes, moving the lamp from side to side so as to illuminate the whole burned area. After ten minutes of treatment the pain subsided, and before the end patient had gone to sleep. The treatment was repeated every four hours for four days, then every six hours for two days and then twice in twenty-four hours for three days. On the eighth day the boy was out, going about as usual, with only slight discoloration of skin. No other treatment was used, except bathing the eyes frequently with warm milk.

Case III. Ivy Poisoning.—A. L., seventeen years old. Severe case involving whole face and neck. Usual remedies had done no good. Applied rays to affected area every three hours during night (there being no electric light available during the day). Pain and itching were relieved at once and patient enabled to sleep. Four nights of treatment sufficed to cure.

Case IV.—R. S., twenty-five years old. Patient especially susceptible to ivy poisoning, which usually lasted fourteen to twenty-one days. Rays applied at once to small area involved on left side of face. Relief was immediate, lasting several hours, when renewed, raying again relieved and for a longer period. Treatments lasted for fifteen to twenty minutes, and were repated four to five times in twenty-four hours. Irritation did not spread beyond area first involved, and patient was cured in less than a week. I had an exceptional chance to observe this case, as it occurred in my own house.

Case V. Tracheitis.—J. M., fifteen years old. This patient had a tuberculous family history, and was herself a hemophiliac. She was of extremely nervous temperament, and even a slight cold would set up a high temperature with paroxysms of violent coughing, and severe pain at the root of the neck, apparently between the larynx and the bifurcation of the trachea. A previous attack in which I attended her lasted ten days acutely, and the irritating cough and pain continued for three weeks, even after a change of climate. All sorts of internal medication, as well as inhalations and external applications, failed to give relief in previous attacks. Within six hours after the commencement of the last attack, due to "catching cold," the Minin rays were applied from a 32-c.p. lamp held twelve inches from the neck for fifteen minutes at a time. Treatment was repeated every four to six hours, and no medication of any sort given. The first treatment relieved the pain, and within twenty-four hours the cough had ceased to irritate. The nervous symptoms, accompanied by rise of temperature, which had always followed the beginning of such attacks, did not appear, and the patient was up and about on the third day. In this case the action of the Minin ray evidently penetrated to the tissues of the trachea and larynx, allaying a sharp irritation of the mucous membrane. This same action is shown even more forcibly in the next.

Case VI.—Mrs. R. T., thirty-six years old. Suffering from phthisis and tuberculous laryngitis. Patient was sent to me by a throat specialist with request to touch the vocal cords with a strong solution of nitrate of silver several times a week. This treatment naturally caused much pain and choking and a persistent metallic taste. It occurred to me to try the effect of the Minin rays applied to the neck before treatment with the nitrate of silver, with the result that the patient no longer felt the pain of the treatment, the choking was reduced to a minimum and the metallic after-taste disappeared.

These cases are but a very few of a large number of varying conditions in which I have been using Minin rays, and I have no hesitation in asserting that we have in this light a safe and reliable means of treating many inflammatory conditions, including joint affections, which have hitherto given the general practitioner much thought and worry.

TROPICAL MALARIA.[1]

BY JOHN V. SHOEMAKER, M.D., LL.D.,
OF PHILADELPHIA;
PROFESSOR OF MATERIA MEDICA, PHARMACOLOGY, THERAPEUTICS AND CLINICAL MEDICINE IN THE MEDICO-CHIRURGICAL COLLEGE.

Since our acquisition of new territory situated within the tropics it has become particularly incumbent upon Northern physicians to give renewed study to the aggravated forms which diseases so often assume in hot climates. It may be anticipated that we shall be brought into more frequent contact with such disorders than we have in the past. The physicians of our Southern and Southwestern States have had much more experience than we in this field. Yellow fever and cholera have occasionally invaded the North, but these visitations are infrequent and most of us in this part of the country have never witnessed an epidemic of those diseases. Sporadic cases of leprosy occur from time to time. I have met with a number in Philadelphia and have reported several in the medical journals. Beriberi has been sometimes brought to our shores by ships from tropical ports. In the Medico-Chirurgical Hospital we have had sailors suffering from that disease, and at our Quarantine Sta-

[1] An address delivered before the Medical Association of the Greater City of New York, October 10, 1904.

tion eleven cases of beriberi were observed by Dr. Judson Daland among a crew of Lascars, certain of which cases showed the presence of the *Plasmodium malariæ*.

Teachers in the North must lay stress upon the subject of tropical medicine, for it may be surmised that, in addition to those who enter the National Services, many will seek civil practice in our new possessions.

During and immediately after our short war with Spain I had an opportunity of observing the more severe forms which malaria exhibits in the tropics. Among the soldiers who were brought to the Medico-Chirurgical Hospital from Cuba, Porto Rico and the camps of this country, were 53 cases of malaria. Many of these were of the ordinary intermittent type with which we are all familiar. A certain number, however, presented a more profound and—in my experience—unusual intoxication, and it is of these latter that I wish to speak, in accordance with the courteous invitation of the president and secretary of your society.

I employ the term "tropical malaria" as indicative of the behavior of the *Plasmodium* in cases occurring in the tropics. The clinical symptoms, accordingly, manifest an intensity which is seldom or never displayed in the temperate zone. The parasite itself is profoundly modified in hot countries. Malignant malarial parasites are particularly confined to the tropical and subtropical regions. With the recognition of the *Plasmodium* and the knowledge of its transmission by the mosquito our conceptions of malarial infection in its different forms have been rendered much more exact. We have, moreover gained an immensely important advantage, in the possession of absolute scientific tests, upon which we may depend in diagnosis. As regards the *Plasmodium* itself, we have learned much concerning its different phases or cycles, within and external to the human body. The parasite propagates itself in the body of the mosquito, is transferred to man and undergoes, in the plasma and red corpuscles, a series of transformations which end in sporulation. It has been discovered that only certain species of the genus *Anopheles* serve as hosts of the malarial parasite. The *Plasmodium* itself exhibits certain differences as regards form, rate of evolution, and the clinical forms of disease to which it gives rise. This classification simplifies considerably the differentiation of the varieties of malaria as it occurs in temperate or tropical climes.

It is possible to distinguish under the microscope many forms of the hematozoa; the flagellate body, the ordinary intra- and extracorpuscular body and the ring form, as well as the crescentic. One of these forms completes its cycle in forty-eight hours and one in seventy-two hours.

The study of the *Plasmodium* in its various phases has enabled us to revise the classification based upon purely clinical phenomena. The malarial paroxysm coincides with the sporulation of a group of the parasites contained in the red blood corpuscles. If *Plasmodium* is present in various stages of development the discharge of the spores and toxins is irregular; the typical periodicity of symptoms is disturbed, the fever assumes a remittent or continuous type, and the temperature charts exhibit a less distinctive zigzag outline. This was illustrated in the more severe cases of which I am about to speak.

A proportion of my cases were of that type which have generally been known as bilious remittent, the estivo-autumnal, or summer-autumn, fever of the Italians.

Our most severe cases were among the soldiers who had served in the field at Santiago and in Porto Rico. Most of the cases were distinguished by severity of symptoms and the irregular course of the fever. All were accompanied and followed by extreme prostration. According to the histories which we obtained, they began more or less insidiously with headache, which was in some instances excessive, backache, general weakness, anorexia; in some cases there had been pain in the neck or all over the body or general soreness; one patient suffered from a dull feeling at the lower border of the left ribs and a pain in the lumbar region. In a number of instances vertigo occurred. In one case it is noted that the eyes suddenly became very painful. Some patients complained of pain in the bones. In some of the men fever had supervened without any well-marked chill. In other histories the chill figures as a prominent feature. One man suffered from a prolonged chill every day, accompanied by fever of the remittent type. Sometimes, but not always, the fever was followed by profuse sweats. The man was exceeding debilitated. One interesting case displayed a chill every morning and every afternoon for two weeks; each chill was succeeded by fever and sweats. The temperature charts departed widely from that of ordinary or benign malaria. In another case the initial chill is described as severe; it had been preceded by intense pain in the head and back, and returned every day for three days. One patient stated that his attack began abruptly with a chill, which was repeated upon the following day. Severe chills were experienced by a number of patients. One man's illness began with a rigor which lasted for half an hour, followed by fever and profuse sweating. His headache was violent. Chills recurred every other day. Upon one occasion the chill lasted as long as two hours. Another patient had a chill every other day lasting an hour and a half, followed by high temperature. One man went to sleep at night with a violent headache and awoke to find himself in a cold sweat, which was followed by a chill and fever, a reversal of the ordinary succession. He was extremely weak. Another patient had a violent chill after having been ill for four days, and subsequently suffered from a repetition of chills every day for twelve days. In many of the cases there was such a blending

of succeeding paroxysms with the febrile rise and fall that the record approached that of a continued fever.

Several cases were accompanied by acute bronchitis. There was cough, with mucoid sputum and pain in the chest; one patient suffered from acute bronchitis two or three days before he was attacked by pain in the head and burning sensations in the eyes, after which chill, fever and sweat developed; the bronchitis continued throughout the case. The history of another man speaks of "a very bad cough." Gastro-intestinal symptoms were marked in a considerable proportion of the patients. All experienced loss of appetite and loathing of food. As a rule, the tongue was heavily coated. Nausea and vomiting were common, and some of the men complained of abdominal pain. Of one patient it is written that he was early attacked with violent cramps, which lasted for four days, being accompanied by fever, nausea and dysentery. The diagnosis of this and three other cases reads: malaria with dysentery. A fifth case is recorded as malaria and diarrhea. Of one man it is registered: abdomen tender but not tympanic. This patient had a severe attack of vomiting. Pain in the stomach, vomiting and diarrhea were the prominent features of another case. In other histories also mention is made of diarrhea. Diarrhea in the begining of the case, followed by constipation, was observed in a number of the patients. Nausea and prostration were so marked in one instance that we administered champagne in cracked ice. The gastric symptoms (vomiting and pain) were so prominent in one patient that the history is headed: Malaria and gastritis. In some attacks the bowels were unaffected; in others constipation was the rule. The spleen was more or less enlarged in most of the men. In some there was tenderness over the spleen without much increase of size.

In several patients the color of the skin was noteworthy. The discoloration varied from a sallow hue to the deepest jaundice and testified to the alteration of the hemoglobin by the malarial parasite and its liberation from the red cells. Many of the cases exemplified the great tendency to recurrence in this variety of malarial fever. After a defervescence of ten days to two weeks the symptoms would return and run a similar course. In many cases there was a decided diminution in the secretion of urine. It was high-colored, contained urea, uric acid, bile-pigment, and, in some instances, albumin. In one case there was hematuria.

Two cases were especially remarkable. The deep yellow shade of the whole body, the vomiting and diarrhea were highly suggestive of yellow fever. There was no genuine black vomit, although the material ejected from the stomach was dark in color. These men lay in a state of stupor attended by low delirium.

Such is a brief analysis of the chief features of the malarial cases from the West Indies. Brought into the hospital intermingled with five times as many typhoid fever patients, it was necessary to be extremely careful in framing the diagnosis and distinguishing between the two classes of patients. The tracings of the chart were not very dissimilar to those of typhoid fever, and the occurrence of abnormal tenderness with diarrhea and extreme debility might cause hesitation. So suggestive was the analogy in some instances that the clinical notes particularly specify the points of difference; of one patient it is said: no nose-bleed; no rose-colored spots. Of others we read: no rose-colored spots upon the abdomen; no tympanitis; no bronchitis; no tenderness or gurgling in the right iliac fossa, and absence of the Widal reaction. Fortunately for accuracy we are no longer dependent solely upon clinical observation. The presence, on the one hand, of the *Bacillus typhosus* and the evidence of Widal's test, and on the other the detection of the malarial parasite, sufficed to settle the diagnosis respectively for typhoid fever or malaria. The cases in which the skin was so dark in hue were distinguished from yellow fever by the continuation of high temperature (that of yellow fever runs a shorter course); and, above all, by the presence of the *Plasmodium malariæ* in the blood. Judging from the cases which

Chart of Case I.

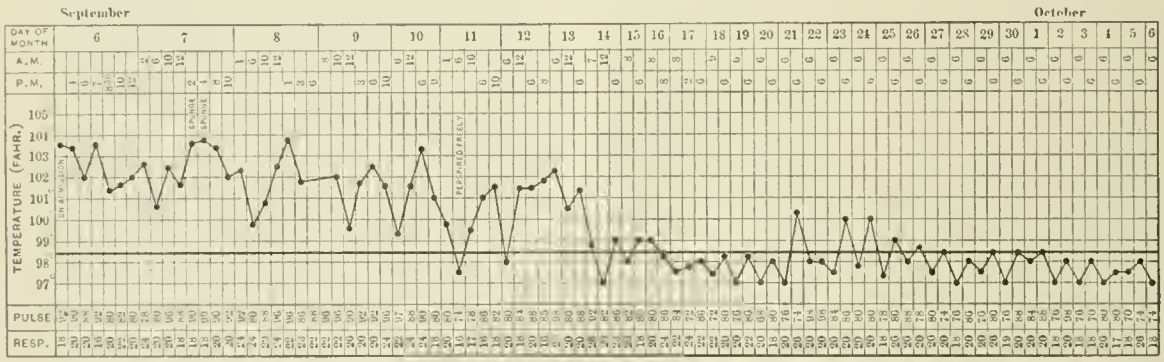

Chart of Case II.

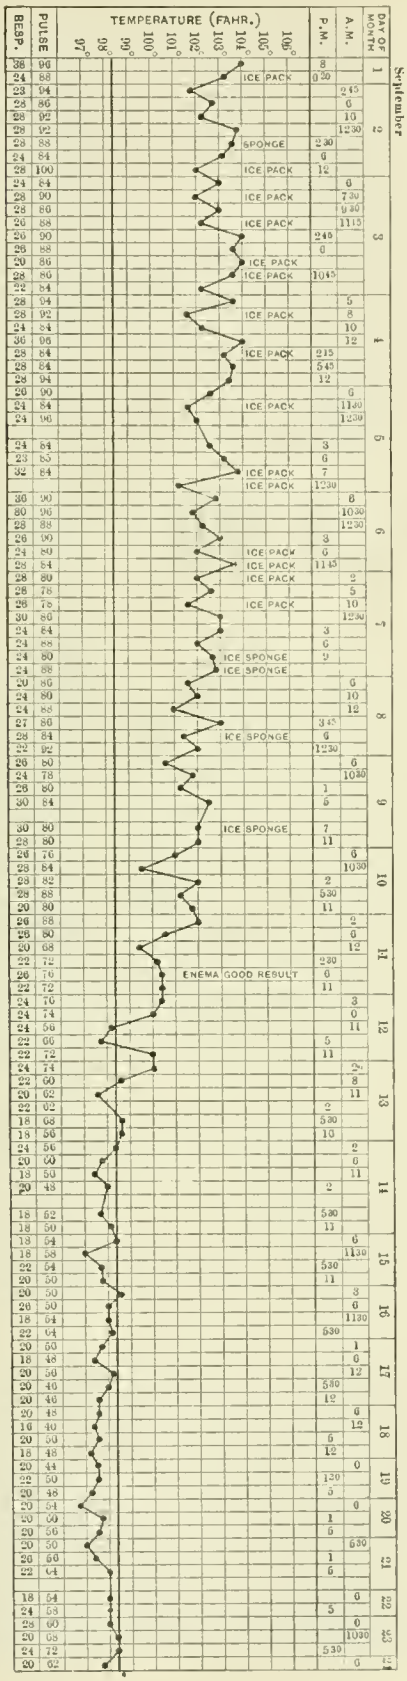


came to us, I should infer that prior to Laveran's discovery in 1880 many cases of severe malarial intoxication were confused with yellow fever. Both diseases, moreover, prevail at the same season of the year. Furthermore, yellowness of the skin is sometimes absent in yellow fever. In yellow fever the pulse is more slow than in malaria, albuminuria is almost invariable, the face is flushed, the eyes brilliant, and the mind is usually clear.

Again, purely from clinical study, it would be difficult, if not impossible, to distinguish between some of our malarial cases and typhoid fever. In both there was diarrhea or constipation; in both there was enlargement or tenderness of the spleen; there was great prostration of nervous and muscular strength and there was delirium in both classes of cases. Our severe malarial cases had contracted the disease in the tropics, they were brought to us after having suffered from the intoxication for two weeks or more, some were suffering from a relapse, and all were in a condition of extreme debility. As regards the differentiation of severe malaria and typhoid fever, we are told that until recent years typhoid in the East Indies was generally regarded and treated as malarial fever. Thus this comprehensive type of intoxication—malaria—may simulate yellow fever at one extremity of its field while at the other it bears a resemblance to typhoid fever. It is a happy circumstance, indeed, that in two out of three distinct diseases we are in possession of absolute and scientific tests which certify to the differential diagnosis.

Case I.—P. V., male, aged twenty-seven years; admitted to Medico-Chirurgical Hospital August 6, 1898, discharged, cured, October 16, 1898. Diagnosis malaria (remittent).

Case II.—J. W. S., male, aged twenty-three years, admitted to Medico-Chirurgical Hospital September 1, 1898; discharged September 24, 1898. Diagnosis, typhoid fever.

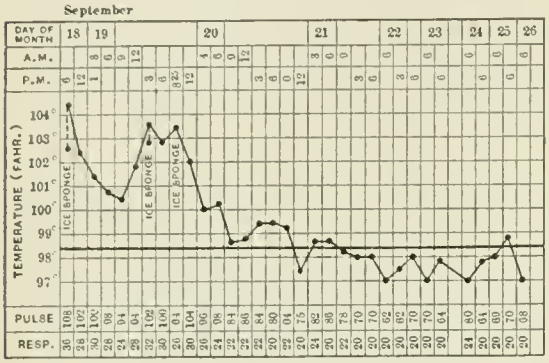
Case III.—A. W., male, aged nineteen years; admitted to Medico-Chirurgical Hospital September 18, 1898; discharged September 26, 1898.

Case IV.—W. M., male, aged thirty-five years; admitted to Medico-Chirurgical Hospital, November 4, 1898; discharged December 15, 1898.

In the treatment of these severe cases of tropical malaria quinine was our main reliance. In our worst cases, however, the stomach was so irritable and vomiting was so incessant that the drug was not retained when given by mouth. Under such conditions I made use of suppositories containing quinine. In cases accompanied by constipation small repeated doses of calomel placed upon the tongue produced movement of the bowels and at the same time allayed the gastric irritability. The rectum, when not clogged by feces, is a good absorbing surface. In cases of gastric ulcer, for instance, life has been sustained for weeks and months entirely upon nutritive enemas. Injections containing quinine in the proportion of ten grains to the

ounce of water with the addition of a few drops of acid to promote solution, have likewise been employed in similar cases. Suppositories, however, can be put in place with less disturbance of the patient, and we know by practical proof that their active ingredient is absorbed. They produce their constitutional or physiological effects.

Chart of Case III.

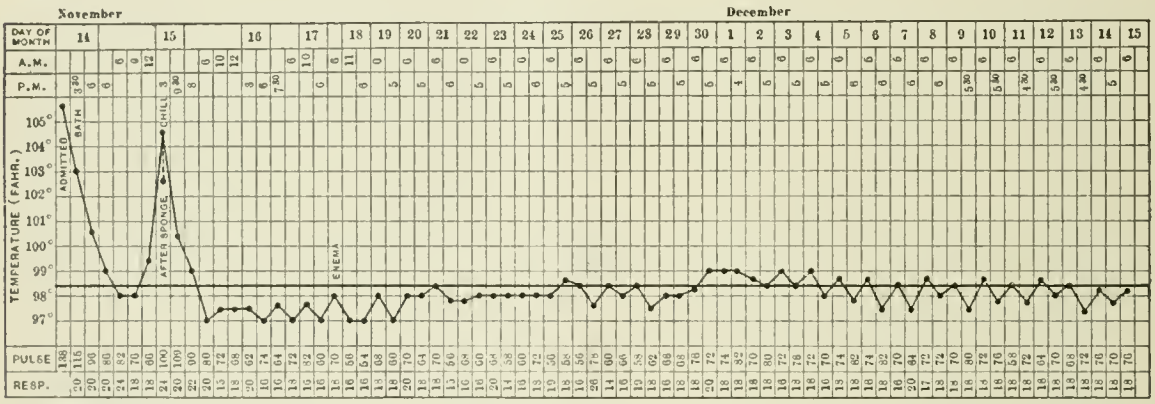


As a rule I employed a 5- or 10-grain quinine suppository every two or three hours, according to the severity of the symptoms and endeavoring to anticipate the paroxysm, *i.e.*, sporulation, by the introduction of as large an amount of the drug as possible. Under the influence of this agent, given in this manner, the tendency to chills was reduced, the functions of the bowels and kidneys were promoted, and the gastric irritability gradually subsided. In some cases, and to meet certain indications, synergistic agents were associated with the specific remedy. When diarrhea was present, I combined equal quantities of quinine and salol with good result—usually five grains of each drug. The antiseptic and antipyretic properties of salol rendered it of material assistance to quinine in checking the diarrhea and reducing the temperature. In some cases ipecacuanha, in one-quarter grain doses, was incorporated in the suppository, conjoined with the quinine; this union lessened the irritability of the intestinal mucous membrane and increased the secretions; it had also a sedative action upon the nervous system.

When nervous symptoms were prominent cannabis Indica or monobromated camphor was combined with the quinine. While the quinine destroys or renders the parasite inactive, the other drugs are useful in raising the tone of the central nervous system and relieving the morbid excitability which resulted from the malarial intoxication. Indian hemp possesses valuable antispasmodic properties. Camphor likewise produces a similar effect upon the nervous system. In monobromated camphor with quinine we have an excellent combination of stimulant and antispasmodic qualities. These drugs, given together, allay restlessness and strengthen the heart, the functional activity of which was seriously depressed in the cases of which I speak. If the bowel was irritable, I used an enema of starch water and laudanum before inserting the suppository.

When the fever was high the patient was sponged. In the worst cases it was necessary to place the patient upon a milk diet. Notwithstanding the profound malarial intoxication of some of these cases yet, happily, none had a fatal termination.

Chart of Case IV.



The principal points in this series are the gravity of the cases, the very marked and prolonged debility which the disease produced, the resemblance of some to yellow fever and of others to typhoid, the diagnostic value of the scientific tests, and the efficacy of quinine administered in the form of suppositories when the stomach is intolerant.

Medical Schools to Amalgamate.—It is stated that the Hahnemann Medical College will soon absorb the Chicago Homeopathic Medical College. Dr. George F. Shears, the present head of the Hahnemann, will be the President of the combined colleges. The Chicago Homeopathic Medical College, in merging with the South Side institution, loses its identity. It is believed that this is the first step toward the addition of a homeopathic medical department to the University of Illinois. The combined enrollment of the two affiliated institutions will approximate three hundred; the property is valued at more than $400,000.

MEDICAL PROGRESS.

SURGERY.

Technic for Intestinal Anastomosis.—Until the ideal method is finally reached, there will unquestionably be a continuance of the suggestions for altered and improved technics in this field. FREDERICK HOLME WIGGIN (*Lancet*, November 19, 1904), in a leading article, discusses, (1) a modified method of invaginating the appendix, and (2) a method of intestinal anastomosis, which is a modification of that of the late Prof. Maunsell. The writer has employed the method of anastomosis as originally devised by Maunsell many times, between 1893 and 1897. During this period, it became evident to him that the making of the secondary slit and the subsequent invagination of the cut ends was an unnecessary complication. The technic which he devised and which he has subsequently used on many occasions, was as follows: The portion of the intestines to be excised is exposed freely without the abdominal cavity. It is then emptied of its contents above and below the damaged spot, and the usual clamps are adjusted on either side of the damaged portion. The mesenteric vessels are tied before being cut and the wound in the mesentery is closed by means of interrupted sutures. After the divided ends of the intestine have been disinfected with hot saline solution and hydrozone, the ends are united by two sutures, which are passed through all the intestinal coats. The first suture is placed at the interior of the mesenteric border and is passed in such a manner as to inclose a portion of the mesentery on both sides. This is tied in the bowel and the ends are left long, so that by it and its mate, the intestinal sutures can be held in place while the other sutures necessary to complete the union, are being put in. This mate suture is placed directly opposite at the highest point of the superior border. These two sutures are so held as to make the parts taut. A third suture is passed simply for convenience between the first two and in a similar manner. Its ends, however, are cut short after it has been tied. The parts are then sutured through and through from within outward and piercing all the intestinal coats, then back through the peritoneal, muscular and mucous coats to the interior of the other segment of the bowels. Seven sutures can be conveniently placed, making nine in all. This unites half the circumference of the divided bowels. The remaining 180 degrees can be conveniently covered by placing a suture half way on the ununited end, leaving its ends long and using them to hold the tissues while the parts are sutured as before. This suturing is continued until the last one is to be placed, when a Lembert is substituted. When the sutures have been properly placed, it will be found that the peritoneum is turned in and that, with the exception of the last one, they are not visible. If, for any reason, they can be seen, they should be covered by a reinforcing Lembert stitch. The bowel should then be washed with a 50 per cent. solution of hydrozone, in saline solution, then with saline solution and returned into the abdominal cavity. This should also be washed and filled with the normal saline solution before the abdominal wound is closed.

Operative Treatment of Perforating Gastric Ulcer.—There is no question that the main element tending to success in operating for this lesion is an early diagnosis. A. B. ATHERTON (*Annals of Surgery*, November, 1904) states that on September 19, 1894, he operated to close a perforated gastric ulcer. This was the first occasion upon which this had been successfully accomplished on this continent. The chief reliance, in the opinion of the author, should be placed on the location and severity of the pain together with the board-like hardness of the muscles. Considerable help is also afforded by the previous history of dyspeptic symptoms. Not much dependence can be placed on liver dulness, neither can the presence or absence of the symptoms of shock be looked upon as at all important. Usually more or less will be found at the onset, but this is not always true. Some vomiting usually occurs and a little blood may be found in the vomited material.

Fractures of the Base of the Skull.—Rawling's recent extensive work on this subject has given a fresh interest and impetus to it. GEORGE L. WALTON (*Annals of Surgery*, November, 1904) concludes, as a result of a study of fifty cases of basal fracture autopsied recently at the Massachusetts General Hospital and at the Boston City Hospital, (1) that in a majority of the cases the basal fracture resulted from impact received in the horizontal plane of the skull, whether upon the frontal or the occipital region or upon the side of the head. (2) While certain of the basal fractures extended from the vertex, there was no suggestion of the contre-coup of earlier writers. (3) The line of fractures tended to enter the fossa nearest the point of impact, and to extend in the general direction in which force was applied. (4) The line of fracture in traversing the base tended to follow lines of least resistance, and in twenty-two of the fifty cases, these lines corresponded more or less accurately to those indicated by Rawling, but the exceptions were too marked and too constant to allow the establishment of fixed rules. (5) The sella turcica was implicated in 36 per cent. of the fractures. The petro-occipital and masto-occipital sutures furnished common lines of least resistance. Fractures extending across the base tended to run parallel to the petrous portion of the temporal bone and through the sella turcica. Certain blows on the occipital tended to cause a line of fracture extending to the jugular foramen or across the petrous bone. The portion of the petrous bone containing the auditory apparatus showed itself peculiarly liable to fracture, more often transversely than longitudinally. (6) In seven cases (14 per cent.) the fracture was limited to the base after vault impact in the horizontal plane. Neither Rawling's theory of transmitted force nor the theory of bursting fracture of Von Wahl and others suffices alone to explain these cases. The results of experiments with bodies of simpler structure would suggest the bursting principle of transmitted force in case of blows, while both play an important part in case of falls. (7) The orbital foramen was implicated in 21.4 per cent. of the cases of orbital fossa fracture. (8) Inequality and immobility of pupils, or both, furnish the most frequent and unfavorable sign of fracture of the base. In the forty-four cases in which the pupils were recorded, they were normal in only thirteen. (9) Injury to the ciliospinal tract in its intracranial course is a more probable cause of the Hutchinson pupil and the other pupillary damages than injury to the third nerve or to the cortex, though no single lesion explains all cases. (10) The reflexes may be lessened or lost in fracture of the base, as in any case of violent jarring of the brain. On the other hand, they may be increased even to spasticity, probably through direct pressure on the pyramidal tract, as by hemorrhage. It is probable that the initial result of the impact in all cases has a tendency toward

lessening or loss of the reflexes. (11) Profuse and persistent bleeding form the ear does not suggest middle meningeal hemorrhage.

New Operation for Intestinal Stenoses.—Every one is bound to read with increasing interest the progress of the ingenious devise for securing intestinal anastomoses known as the elastic ligature. Theodore A. MacGraw (*Annals of Surgery*, November, 1904) in a fully illustrated article demonstrates that the width of the field of its utility has by no means yet been explored. Having shown how certain of success this devise is in establishing anastomoses and struck with the experience of all surgeons that resections of the colon are followed by a very high rate of mortality, he has endeavored to apply his device to this part of the gut. Wolfler in 1806 stated that 54 per cent. of resection on the large and small intestines resulted in death. It has been definitely shown that the mortality rate varies constantly with the position of the site of operation. The lowest rate being in the ileocecal region, the next safer area being the sigmoid. All radical operations on the transverse colon and the flexures have been attended with a high percentage of deaths. From a careful study of the subject, the author believes that this high mortality rate is due almost entirely to the inability of the surgeon to isolate the transverse portion as well as the two extremities of the great gut. Infection of the abdominal cavity is in most cases the source of death. Furthermore, in view of the fact that half of the colon cases die, it is but natural that surgeons have hesitated in the past to operate until they were absolutely driven to it. As a result of this, many cases have been operated on which were nearly moribund. For this reason the German surgeons resorted long since to an operation in three stages. Obviously, however, although of 12 cases so treated by Mikulicz, ten recovered, the method is so slow as to be of questionable value, and furthermore, it is needless to state that a condition requiring three operations for its relief calls for serious study. The first and essential considerations are that the abdominal cavity be protected from infection by deferring the evacuation of the intestinal contents until the closure of the abdominal wound. Second, the avoidance of secondary operations. The physical examination of the patient should be most careful and complete, the abdominal peristalic wave being one of the surest aids in locating the seat of the trouble. Distention of the lower colon and sigmoid by gas or fluid in fat people is also advised. Having located the tumor, operate directly over it. The coil in which it is located should be drawn out of the abdomen, two limbs of the intestine leading to and from the tumor should be joined together by Lembert sutures and an anastomosis be made with an elastic ligature. The wound is now closed snugly around the protruding coil, the ligatured portion remaining in the abdomen and the tumor with two or three inches of gut outside. A firm silk ligature should be tied around the efferent limb just below the tumor and the gut cut off below it, care being taken that none of its contents soil the wound. On account of the obstruction above it, this part of the gut is always small and is easily handled. It is now closed by an invaginating suture and pushed in until its outer surface no longer projects. The skin is then brought over it and sutured. In this way the efferent limb is entirely disposed of. The efferent limb is now treated as follows: An ovarian trocar is thrust into the intestines and the feces discharged. As soon as this has been accomplished, the diseased portion is removed and a large glass tube inserted into the bowel and tied in place. At the end of four or five days the feces will pass through the anastomosis established by the ligature. The tube may then be removed, the gut sutured and invaginated and the wound of the integument closed over.

PATHOLOGY AND BACTERIOLOGY.

Experiments on the Dissemination of Tuberculosis in the Female Genitals.—This question has been subjected to animal experiments by P. Baumgarten (*Berl. klin. Woch.*, October 17, 1904). The results were quite uniform in the 50 rabbits employed. The material used was the bacillus of the "perlsucht," either as an emulsion or bits of the nodules. The lower and upper parts of the vagina and the horns of the uterus, and also the pelvic peritoneum were infected by injection or incorporation of the whole tissue. Although a severe tuberculosis of the pelvic peritoneum followed in the cases so infected, the tuberculous inflammation never once invaded the genital tract proper. It was also found that infection from the cornu of the uterus never traveled outward but always downward into the uterus. Infection of the lower segment of the vagina developed into a limited inflammation which did not go beyond certain borders but regularly invaded the urethra, although it did not extend beyond the sphincter of the bladder. The bladder, ureters and kidney remained uninvolved. Infection of the upper part of the vagina remained localized. The infection which started in the horns of the uterus also extended into the upper segment of the vagina, but never any lower. This shows that tuberculosis in this region, like that in the male, follows a definite course and is limited to definite anatomical bounds. In tuberculosis of the male genital tract, the dissemination follows the direction of the seminal current, and in the female it follows the course of the ovum from the ovary into the vagina. In the urinary tract likewise, the infection follows the course of the urinary flow. There are two localities where the tuberculous infection may spread from one to the other system. In the male this is the prostatic portion of the urethra and in the female, the urethra and the lower vagina.

Latent Microbic Infection.—The question whether the internal organs of healthy animals harbor germs has been answered both in a positive and negative sense, but has been finally settled by the careful experiments of A. Wrzosek (*Virchow's Archiv*, Vol. 178, No. 1). When fairly large-sized pieces of liver, spleen, mesenteric glands, etc., were transplanted with all aseptic precautions, a growth was obtained in a large percentage of the cases. Accidental contamination was ruled out, for a control culture showed that the germs in the air were different. Another series of animals was fed with food purposely inoculated with certain harmless saprophytic bacteria which do not normally occur in the intestinal trast. In 30 out of 47 experiments, the same organisms could be isolated from the mesenteric glands, liver, spleen, kidneys, bronchial glands, lungs, bone-marrow and muscles. Experiments were then made to ascertain by which route their various organs were infected, but the contents of the thoracic duct and the blood from the mesenteric veins were found sterile in all instances. This the author explains by the well-known bactericidal action of the lymph which prevents the development of germs when brought on culture-media. When the animals were fed with germs after the thoracic duct had been ligated, the inter-

nal organs were never found infected, which proves without doubt that the thoracic duct is the normal route. Most of the germs normally found, are probably derived from the intestinal tract; the lungs certainly play a subordinate rôle since the conditions for absorption are less favorable and most organisms are prevented from reaching the alveoli by the ciliated epithelium and the normal secretion of mucus. In the light of the above experiments the occurrence of a primary renal tuberculosis, a suppurative meningitis after exposure to the sun's rays or a cryptogenetic sepsis, would be easy to explain. The germs were already present but simply gained a foothold owing to diminished local or general resistance.

Cause of Aleppo Boil.—In the excised nodules of a typical case of Aleppo boil, E. J. Marzinowsky and S. L. Bogrow (*Virchow's Archiv,* Vol. 178, No. 1) discovered peculiar epitheloid bodies with chromatic nuclei within the cells. The secretion also contained these bodies, generally inclosed in a vacuole within the epithelium and only rarely in leucocytes or red blood cells. Stained with methylene-azur, two kinds of chromatin could be detected, one at one pole, of pale lilac color and another in the center, more intensely reddish lilac. In all probability the structure is a protozoon, closely allied to *Trypanosoma.* All attempts at culture, especially in hay-infusion, were negative. The authors apply the name *Ovoplasma orientale* to the parasite and believe that infection occurs through the bite of insects.

Relation of Paget's Disease to Carcinoma.—H. C. Jacobäus (*Virchow's Archiv,* Vol. 178, No. 1) concludes an interesting article by stating that Paget's disease is a carcinoma from the very beginning, starting from the glandular epithelium of the excretory ducts. The peculiar epidermal changes depend upon proliferation of the glandular cancer within the epithelium. The so-called Paget's cells are emigrated cancer cells; the proof of this is to be found in the fact that similar epidermal changes occur if an ordinary glandular cancer ulcerates through the skin. The slow and apparently benign course of the initial growth is due to the resistance offered by the fibrous and smooth muscle tissues. For the same reason, a cancer beginning in the deeper portions of the gland, does not readily reach the surface and gives rise to Paget's disease.

Bacillus Violaceous Manilæ.—According to a report from Manila, a new pathogenic micro-organism, the *Bacillus violaceous Manilæ,* has been discovered by P. G. Woolley (Bur. of Goverm. Lab., 1904, No. 15). The organism is a short rod staining with the usual aniline dyes, but discolorized by Gram's method. Certain clear spaces are noticed in the interior which are not tinged by the methods used for staining spores. The organism is motile and possesses one polar flagellum. On agar plates, small, round, violet-gray colonies appear in twenty-four hours, which gradually enlarge and deepen in color. Gelatin is liquefied and broth diffusely clouded. On potato, the pigment produced is luxuriant. Milk is rendered slightly acid but not coagulated. The bacillus had been isolated from three cariboos which died suddenly with symptoms of acute hemorrhagic septicemia. A very small amount of the living organism caused death of small animals and produced specific lesions without the appearance of any appreciable immunity. At the site of inoculation there is generally a wide area of necrosis with edema. The lesions in the parenchymatous organs are miliary abscesses which may show a suppurative stage. In the lungs and liver the surfaces of the abscesses may be covered with a fibrinous exudate. The bacilli are found in all lesions. The losses in stock are slight, so that there is little danger of an epidemic.

EYE, EAR, NOSE AND THROAT.

Researches on Temperature of the External Ear.—Winternitz was the first author who stated that he found that as the result of careful measurements, he was able to diagnose a regular afternoon rise of temperature in the external auditory meatus, which dropped again at night. E. Sommer (*Berl. klin. Woch.,* September 26, 1904) has recently made some observations with the very delicate thermopalpatory apparatus devised by Hertz. This shows only relative values but is exceedingly sensitive. It was found that the curve described by Winternitz does not regularly exist, but that there is a constant difference between the temperature of the two ears, the left one being invariably the warmer. This cannot be appreciated by the sluggish mercury thermometer, but only by the delicate instrument noted. It seems likely that the higher temperature may be associated with the greater activity manifested by the left half of the brain and the more active circulation of this region. The author concludes that further observations in this field may lead to a means for assisting in the localization of intracranial lesions.

Lithemic Nasopharyngitis Due to Systemic Disturbance.—Many cases of nasopharyngitis are due to a lithemic state, according to J. A. Stucky (*Jour. Am. Med. Ass'n,* October 15, 1904). An index of this condition is the presence of indican in the urine, with an excess of uric acid. Treatment should therefore be directed to the constitutional state and special attention be given to clearing out the gastro-intestinal tract. The patient is put on a restricted diet with plenty of water. Before the evening meal the colon is flushed out with several quarts of soap suds and on retiring, eight ounces of warm olive oil are injected high up into the rectum and allowed to remain. If there is much muscular tenderness or general malaise, strontium salicylate is given in ten-grain doses every two hours. Meats, sweets and salads are to be avoided, alcohol denied, water taken freely between meals, the skin kept active and exercise insisted upon.

Heredity and Treatment of Convergent Strabismus.—From a series of over 2,000 cases examined and 700 operations performed, during the past forty years, H. Cohn (*Berl. klin. Woch.,* October 22, 1904) presents the following recommendations: Up to the fourth year the healthy eye should be bandaged for several hours daily. During the fifth year, special exercises should be begun with convex lenses and the stereoscope. The total hyperopia should be constantly corrected. Operation should not be undertaken before the tenth year, and only in cases of extreme deformity should tenotomy be done during the sixth year. It is well not to promise a cure but only improvement. In severe cases the external oblique may be advanced. From the histories of 2,700 private patients, Cohen finds that in 23 per cent. of the cases some near relative was affected in a similar manner.

Rupture of the Ear Drum by Lightning.—A peculiar accident is recorded by K. Burkner (*Ber. klin. Woch.,* June 20, 1904), of actual laceration of the drum membrane by a bolt of lightning which struck a tower in which the patient in question happened to be. Examination of the ear showed an extensive tear in the membrane, part of which was folded over the handle of the malleus, and from the nature of the injury it was evident that it could not have been caused by the fall which the boy had. The truth of this conclusion

was shown by its contour, the slight amount of hemorrhage, the absence of symptoms referable to the labyrinth, and also by the fact that the only other injuries on the head were the burns caused by the flash. Very few cases of this kind have been recorded, and the author is doubtful whether the laceration was due to concussion or to the electric spark directly or to the shock attending the sudden discharge of electricity from the body. Healing took place and the boy's hearing was restored.

Inspection of the Antrum of Highmore.—It is confessedly true that the present means of differentiating antral disease give no information save as to the presence or absence of fluid in the cavity. A. Brown Kelly (*Lancet*, September 17, 1904) states that it is as illogical to treat antral disease in this blind fashion as it would be to attempt to manage otorrhea without examination of the ear. The method of opening the antrum is as follows: The gingivolabial fold beneath the canine fossa is painted with 20 per cent. solution of cocaine. Forty-six cubic millimeters of a 10 per cent. solution are then injected into this area. An incision is then carried through the fold for about two centimeters. By pushing up the soft tissues, the facial wall of the superior maxilla is easily exposed. A sharp trocar is then applied to this surface at a point about five millimeters in front of the zygomatic-alveolar ridge and about the same distance above the incision in the mucous membrane. The trocar is directed backward, upward and inward. The operation is often painless, although the bone section is not always so. If the incision is made as recommended, the small arterial twig, which is located immediately posterior to it, is avoided. Should this escape, the bleeding is unimportant. A trocar of good size should be used rather than a chisel, because the latter jars the patient's head. An ordinary aural or nasal speculum is then introduced into the opening. The end of this speculum should be beveled. Immediately on introducting this instrument the posterior wall of the antrum is seen. By inclining it from side to side, the entire cavity may be minutely inspected. The view of the inner wall of the antrum, seen as it is in perspective, is not good, and the osteum can rarely be made out. The condition of the lining membrane is of the utmost importance and should be carefully inspected. It is well, however, to postpone detail examination until twenty-four hours after, the wound being packed in the mean time with iodoform gauze. The pain is usually insignificant. The cheek may swell to a very considerable extent, so much so in fact, that the eyes may close. The author has opened over forty antra in this way without any serious consequences and with great advantage to the patient and with satisfaction to himself. As already intimated, the chief changes found in this series were lesions of the mucous membrane. Polypoid degeneration of this membrane was found in three cases while polypæ occurred in but one. It was a pedunculated multilobular polypus the size of a bean, which hung from the inner part of the roof and, curiously enough, was met by a similar growth twice as large which rose from the floor.

PRESCRIPTION HINTS.

Bronchopneumonia in Childhood.—It is necessary to estimate at the outset whether the disease is chiefly bronchiolitis, or if there is much consolidation, writes Douglas Stanley (*Birmingham Medical Review*, October, 1904). Also, whether it is due to an ordinary "cold," or part of a specific disease, or occurs in a debilitated or rachitic child. If it is chiefly bronchiolitis, there are two indications, viz., to prevent increase of the catarrhal process, and to free the tubules of obstruction. The child must be put to bed in an airy, cool room, on a diet of milk diluted with barley water or vichy, or, if older, on boiled bread and milk and such food. The following may be given every four hours:

℞ Vini ipecac. .....m v-x (0.35-0.7 c.c.)
Spiriti ammon. aromat....m v (0.35 c.c.)
Syrupi tolutani .....m v (0.35 c.c.)
Aquæ q.s. ad.....3 ii (8.0 c.c.)

After three or four days, if the child improves, the following may be substituted, given thrice daily:

℞ Vini ipecac .....m iii (0.2 c.c.)
Syrupi glycerophosphat ad .....3 i (4.0 c.c.)

If the case is of medium severity with fair consolidation, a pneumonia jacket should be applied and twenty minims (1.3 c.c.) of wine of ipecac given every seven to ten minutes till vomiting ensues, but not exceeding four doses. The following prescription is given every four hours:

℞ Vini ipecac. .....m v (0.35-0.7 c.c.)
Spt. ammon. aromat. } ..aa m x (0.7 c.c.)
Syr. senegal }
Syr. tolutani .....m xv (1.0 c.c.)
Aquæ q.s. ad. .....3 ii (8.0 c.c.)

If the bronchial element in the breath sounds is marked, ten minims (0.7 c.c.) of spt. ætheris nitrosi may be added with advantage. If in thirty-six hours there is no improvement, one minim (0.06 c.c.) of creosote may be added, and a warm solution of sodium bicarbonate used as a spray. For the very severe cases it is wise to put up a tent-bed and use a steam-kettle with eucalyptus or pine needle oil added. The former prescription may be increased by

℞ Strychninæ sulphat. .....gr. 1/50 (0.0012 gm.)
Spt. ætheris .....m xv (1.0 c.c.)

A cold pack may be necessary, cold affusions to face and chest, or it may be well to seat the child in a bath of hot water up to the waist. Pure brandy, m xv (1.0 c.c.) may be added to the milk and given every two hours. If the temperature is unusually high at the outset, tepid sponging and the following should be resorted to:

℞ Liquor ammon. acetat .....m xv (1.0 c.c.)
Spt. ætheris nitrosi.....m x (0.7 c.c.)
Ammon. bromid. .....gr. v (0.35 gm.)
Syrupi. .....m xx (1.3 c.c.)
Aquæ .....q.s. ad 3 ii (8.0 c.c.)

It is better to avoid aconite. If vomiting and diarrhea are disturbing, the milk may have to be replaced by whey or albumin water or cold chicken broth. Also may be given:

℞ Bism. salicylat. } .....aa gr. v (0.35 gm.)
Sodii bicarb }
Bism. subnitrat .....gr. x (0.7 gm.)
Chlorodyne .....m x (0.7 c.c.)
Pulv. tragacanthæ comp.....gr. xx (1.3 gm.)
Aquæ .....q.s. ad 3 iii (12.0 c.c.)

and Dover's powder, gr. ss to ii (0.03-0.12 gm.) may be added if thought advisable. Poultices should never be applied; they are often dangerous. Emphysema plays an important part in adding to the respiratory and cardiac embarrassment, and in such a condition oxygen may be of value. During convalescence cod-liver oil or the hypophosphites may be administered.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, DECEMBER 17, 1904.

COLLEGE GRADUATES IN MEDICINE.

YALE University has lately published some very elaborate studies concerning the careers of her graduates. It is conclusively shown, as far as this university is concerned, that a smaller proportion of her students become professional men than a century ago, but this proves nothing. We may safely say that a larger proportion of professional men exists in each community than ever before. The mere fact that a greater number of graduates enter business means only that a century ago a young man that was preparing for business thought a university training quite out of his line; and it was only the predestined professional man who thought of going to college.

The graduates who indulge in a financial career represent grandfathers who went without a college education; their presence at college does not alter their predestined relation to the business world. The statistics mean not that more college-bred men are choosing business instead of a profession, but that more business men are college bred than heretofore.

The statistical report on physicians is what interests us most. At Yale the lawyer is in the ascendant. Out of the living graduates of the university to-day thirty per cent. are lawyers, eight per cent. physicians and seven per cent. ministers. But either the physician is more successful financially than the lawyer and the minister, or else his calling is not so arduous, for whereas one out of ten of the living physicians who were Yale graduates have gone into business, nearly one-fourth of the ministers as well as the lawyers have given up their professional life for that of finance or teaching.

The minister's point of view is well discussed in the current issue of the *World's Work*, by Everett T. Tomlinson, in his article on "The Decline of the Ministry." He attributes this to the poverty of the minister, the petty and irritating work he is obliged to do in addition to, and to the detriment of his preaching, the lack of freedom in honest conviction and the degrading sense of being part of a "beneficiary system." Certainly the physician has none of these troubles to combat. He may be poor, but his income is not limited to a meager salary. He may be obliged to minister to petty and ignorant people, but they are not banded together with power to dismiss him from their conjoined service. His theories may be criticized, but they do not damn him, and when he sends out his bills he is much more apt to be aware of his position as a dispenser instead of a recipient of charity.

In fact, there has never been a time when the study of medicine has been so promising as it is at present. It is true that there are more doctors in a city block than can be comfortably maintained by the citizens thereof; but that is not the point. The study of medicine has passed the stage where its remuneration is confined to the practice of it. It has become fundamental in daily life. This is the era of preventive medicine and sanitation, of laboratory research and applied science. There are ten avenues with good remuneration open to the young physician to-day, where twenty years ago there was nothing but the house-to-house call and the clinic. The opportunity lies with the physicians themselves. There are tuberculosis sanitaria to be established all over the country. There are methods of inspection for contagious diseases in schools and factories, and great business houses to be established. There are tenement problems to be met. All these and many more have passed the first stage of charitable endeavor and sentimental interest. They have become as essential to civic life as is a corporation's legal counsel, and the

opportunity is open to the energetic young physician to broaden his professional horizon by bringing modern medical science into the city as well as into the household.

Again, there is over and above all this too much of genuine satisfaction in the study of medicine to permit of many desertions. The hand-to-hand conflict with disease is a stirring combat and the mental satisfaction of the new discoveries with the microscope and test tube lend a zest to living that is satisfying to a high type of mental culture.

THE ACID INTOXICATIONS.

By slow degrees and with much travail is nature delivering up the mysteries of her more involved chemical processes. While for many years we have written exhaustively on the oxidations and reductions that take place in the human body and of their relation to diseased states, it may be said that we are as yet only in touch with the earliest stages of the birth of correct ideas concerning these processes.

One type of perverted chemisms has been termed the acidoses, or acid intoxications, and the researches of Magnus Levy, Herter, Von Mering, Minkowski and others, have advanced to such a stage that they offer practical guides to treatment, particularly for the more flagrant or pronounced states of these forms of slow poisoning.

It is recognized that two important factors enter into the acid intoxications. Such acids may, in small part, be absorbed from the stomach from foods, etc., but these are of much less moment than the organic acids that are formed as the result of damage to the cells of the body whereby the ordinary products of metabolism are not properly oxidized. These oxidations, it is well established, are carried on particularly in the liver cells and in the muscles, but when these cells fail in their full duty organic acids, particularly diacetic and oxybutyric, are formed in comparatively large quantities, and as a result of their non-combustion, they eagerly seize upon the alkalies of the body cells and withdrawing these from the metabolic activities, set up a vicious cycle, whereby cell respiration is very much hampered. For, as it is well recognized, it is necessary for the blood to utilize the sodium of the body in combination with CO_2 to carry on its oxidation functions in the lungs. The sodium, having been largely seized upon by the organic acids, is not available for this most important work, and Pelion is heaped on Ossa to the ultimate causation of disease.

It is gradually becoming apparent that a number of causes bring about the primary increase in the formation of these acids, and an increasing number of affections of a milder or severer grade are being recognized as following in the train of these suboxidations.

As for internal metabolic causes, we are not yet in a position to assert just what are the starting points. Intense intestinal putrefaction is known to set free a series of bodies which cause an increase in the acetone bodies in the system, but those most open for research are found in drugs. Thus carbon monoxide is known to increase the acetone bodies, so also is phlorhizin, which drug induces a type of glycosuria of more than passing experimental interest. From another viewpoint adrenalin brings about a glycosuria, as do also chloroform, ether, antipyrin, morphine, atropine and others.

The exact steps in the process of acid formations by these bodies is not yet outlined, but they each and all are opening up new lines of approach to the solution of the first cause.

The results of these intoxications we have always with us. Some, like arthritis deformans of the non-infectious type, defy all efforts at analysis, and we are compelled to fall back on a hereditary nervous defect, which is hair trigger, as it were, to this type of acid intoxication to account for the trophic disturbances in the joints.

It seems not improbable from general research that the cyclic vomiting of children, the vomiting of pregnancy, and eclampsia, have as one of their etiological factors at least the overproduction of these organic acids, while in diabetes, the classical extreme of complete acid intoxication, is met with.

While the general procedures of the therapeusis of these conditions are only vaguely outlined by the slow accumulation of a rational understanding of the morbid processes themselves, it is not too visionary to hope for much relief in the near future.

For the most pronounced of these diseases, diabetes, the general rationale is now fairly clearly perceived, but it begins unfortunately only after the disease has become established. The knowledge that will lead to the possible prevention of diabetes still is hidden.

Alkalies, to replace the used sodium bases,

careful intestinal hygiene, particularly limiting excessive putrefaction, a diet not too restricted, especially not as to water, but one sparing in fats and carbohydrates, a partial removal of the ban on proteids, and an annihilation of the doctrines founded on the fancied differences in red meats and white meats, these, combined with an open-air occupation, involving mild exercise in a carefully selected equable climate, are the main features of the therapeusis not only for diabetes mellitus, but for practically all of the acidoses.

PNEUMOCOCCUS PERITONITIS.

A WIDER knowledge of this very serious and as yet comparatively little known sequel, of pneumonia, is evidently much to be desired.

Frank S. Matthews, in a leading article (*Annals of Surgery*, November, 1904) states that in all, 106 cases have been reported. He believes, however, that because of the difficulty of positively establishing the diagnosis, and in large measure because of the neglect with which the subject has been treated, a great many cases have not been recognized.

For this reason and because of the fact that the pneumococcus in its multifarious clinical manifestations, seems to be particularly active, and, if we are to give credence to the Board of Health reports, to be markedly and almost epidemically on the increase, the season is timely to draw the attention of the general practitioner to the clinical manifestation of this interesting pathological entity.

Acknowledging further indebtedness to the article already referred to, it may be stated that the lesion is probably three times as frequent in children as in adults. As to the sex, a most remarkable and as yet unexplained relation exists, viz.: Under fifteen years of age it is seven times as frequent in girls as in boys; over fifteen years of age the two sexes are equally affected. This would seem to show that the establishment of the menstrual function had something to do in safeguarding the female. How or why is as yet a matter of conjecture. It would seem to the casual observer that before further explanation for this most extraordinary ratio be sought, efforts should be made to determine that the ratio itself is not one of those interesting vagaries of figures. This, particularly, because the statistics upon which it is based have their foundation on a very small number of cases.

The pathological anatomy is very similar to that of pneumococcus empyema. The exudate is characteristically odorless, highly fibrinous, of a greenish-yellow color and varying very markedly in its consistency.

One very favorable factor in the distribution and localization of this lesion lies in the marked tendency shown by the exudate to localize itself either in the pelvis or in the hypogastrium. This, naturally, militates very much in favor of the patient, because, as is well known, the pelvic peritoneum can better take care of bacterial toxins than any other portion of the sac, and, further, the "walling off" of the process in the region of the umbilicus has, in unrecognized cases, enabled the abdominal walls to part at the point of least resistance, viz., the umbilicus, and allow the spontaneous discharge of the abscess. In most of the reported cases it is of uncommon interest to note that the peritonitis has not been secondary so far as observations went to pneumococcus invasion elsewhere, a least of a demonstrable type.

The clinical picture is, in a measure, characteristic, and typically presents three stages. The first is manifested by tenderness and distention, accompanied by pronounced fever and vomiting. The muscular rigidity and other symptoms are not so marked as in other types of peritonitis. Within a few days the second stage manifests itself by a cessation of the vomiting and a return of the temperature to normal. The patient, as a consequence, looks better, and the attendant is prone to be thrown off his guard. Diarrhea, as a rule, develops in this stage. In a subacute, but relatively rapid manner, the increase of the exudate, however, takes place, the temperature within a few days rises, a tense cystic mass appears in the hypogastrium; there are chills, cachexia, weakness and every other symptom of general invasion and death is almost certain to subvene unless the abscess is opened or spontaneously evacuates itself.

The differential diagnosis of the disease in its later stages is somewhat difficult, unless the characteristic symptoms have been carefuly watched, and, it may be said, unless they have been present. As in many other lesions, typical symptoms do not appear at all. The first stage may necessitate the question being answered whether or not the peritonitis exists at all. This is particularly true of the form of infection under consideration, because paresis of the intestines is rare, and, moreover, because pain and distention are

not necessarily marked. In the second stage, with its diarrhea and slight distention, the clinical signs are not unlike those of typhoid. The terminal stages of the disease simulate tuberculous peritonitis.

Jensen (*Archiv für klinische Chirurgie*, 1903, lxx, 91), states that the source of the infection is not unlike that attributable to other types of invasion, viz., through a wound; through the diaphragm; through the genitals; through the intestinal tract; through the blood; from pneumococcic foci in the abdominal organs. It is interesting that the transportation of bacteria from the lungs through the diaphragm, in case of pneumococcus peritonitis following a lobar pneumonia, unless it takes place indirectly through blood infection, must be brought about by retrograde transportation through the lymphatics. So far as genital infection goes, the phenomenal frequency of the disease in girls has naturally suggested that the germs find their way to the peritoneum by way of the tubes. Nevertheless, salpingitis of a pneumococcus type is extremely rare and has not as yet been reported except in adults.

During the well-marked epidemic of lobar pneumonia, which this city experienced last year, at least one case of this pneumococcus peritonitis developed as a sequel. No less an authority than Janeway considered the diagnosis of pneumococcus peritonitis correct, and, indeed, the pneumococcus was found imbedded in the fibrillar meshes of the exudate. This finding was made and reported from the Cornell Laboratory by Thomas W. Hastings. It is not uninteresting to note, however, that Dr. Hastings was unable to obtain the germ by culture methods. This corresponds with the findings as reported by Matthews, that Netter in 140 cases of peritonitis bacteriologically examined found the pneumococcus but twice.

A point of dissimilarity, however, between the case under consideration and those reported by Matthews, lay in the fact that the exudate was not alone not localized, but was present in extraordinary quantities—nearly eight quarts was removed by trocar. Throughout Matthews's article, he speaks of the exudate being purulent. That it may be distinctly serous and, indeed, have many of the characteristics of a transudate, is not to be doubted, although confessedly the cases presenting this type of what might be called peritoneal pneumococcus hydrops are rare.

The treatment of cases distinctly associated with purulent exudate is, of course, self-evident. Those, however, which from the onset simulate in the later stages of the disease as described by Matthews, tuberculous peritonitis of the so-called wet type, are certainly *sub judice* in the matter of treatment.

It is generally agreed that free incision and exposure to the air with or without drainage will do much toward curing this form of tuberculous peritonitis. When pneumococcus peritonitis develops, as it may do, either without the initial stages described by Matthews, or else passes through them at so rapid a rate that they are not recognized, the most natural question which the practitioner has to ask himself, is whether to relieve the distention by puncture or by open incision. This is confessedly a difficult question to answer, since it is not yet known why abdominal section is curative in the case of the tuberculous infection. From a very limited experience, it may be justifiable to urge puncture and aspiration patiently repeated until this treatment is shown by the increasing rate of fluid collection, to be unavailing. This conservative method has, in the past, proved successful.

ECHOES AND NEWS.

NEW YORK.

New York Academy of Medicine.—At the annual election, held Thursday, December 15, the following officers were elected: Charles Loomis Dana, President; T. Mitchell Prudden, Vice-President; Abraham Jacobi, Trustee; Reginald H. Sayre, Treasurer of Board of Trustees; William C. Lusk, Committee on Admissions; L. Emmet Holt, Committee on Library; David Boyaird, Jr., James Ewing, Charles L. Gibson, Homer W. Gibney and Edward L. Keyes, Jr., Delegates to State Medical Society.

Lecture by Dr. Flexner.—Dr. Christian A. Herter has announced to his class at the College of Physicians and Surgeons, that Dr. Simon Flexner, of Johns Hopkins, will lecture at the College during the present month on "The Action of Snake Venom." Owing to the large number of students who desire to attend, the lecture room cannot be opened to the profession, but an abstract will be printed in the Medical News in the issue following the lecture.

No Mid-Year Examinations at P. and S.—Contrary to the usual custom, no examinations will be held at the College of Physicians and Surgeons at the end of the first half year. This was decided upon at a Faculty meeting held last May and has just been made public. The reason given is that students neglect clinics and other college work during the mid-year to study, and thus for about a week the benches are empty, which interferes seriously with courses given by certain professors. The students are circulating a petition to have the measure annulled and are supported in their effort by a few of the Faculty who wish the old régime continued.

City's Power to Protect Itself.—Much depends, writes the New York *Sun*, on the opinion of the Corporation Counsel on the question propounded to him by Health Commissioner Darlington, concerning his right to revoke the license of a milk distributing firm in this city which has been selling impure milk. The city should certainly have this power to protect itself, for experience has shown that fines are not a preventive of fraud. The large dealers who find big profits in adulteration pay without protest fines of $500 and go right on with their old methods. Dr. Darlington reports the case of one large concern whose head he has haled to court four times and had fined $500. The concern still does business. Now the Commissioner has gone after the dairies, where, after all, the beginning of the evil lies. The results of some of the first inspections have been startling. Flagrant violations of the sanitary laws have been found in large dairies right at our door. In several cases the cows were seen to be milked in filthy stables, and to counteract the impurities that thus got into the milk formaldehyde was used freely. At certain creameries men were found mixing yellow coloring matter in the cream before bottling it. These were cases where the milk was later handled by "high class" dealers, and if such a product is distributed at high prices, what must lesser charges bring the consumer? If the Commissioner has a right to bar the milk of such concerns from the city, the frauds will readily be prevented. If the law does not now give him the right to revoke the licenses of dealers participating in such frauds, it should be amended to do so.

PHILADELPHIA.

Blockley Physicians' Banquet.—The eighteenth annual dinner of the Association of ex-President and Resident Physicians of the Philadelphia Hospital, was held at the Bellevue-Stratford, December 6. Drs. H. C. Wood, D. J. McCarthy, E. M. Welty, G. M. Guthrie and H. B. Calhoun, spoke to toasts. Dr. E. L. Duer is President of the Association.

Site Secured for Cancer Hospital.—The American Oncologic Hospital has secured the lease of property at Forty-fifth and Chestnut streets, the intention being eventually to buy it. Drs. A. Hewson, G. B. Massey and H. R. Swayne have been appointed on the medical staff.

Mont Alto Sanatorium.—The Mont Alto Sanatorium for Consumptives, on the State Forestry Reservation in Franklin County, established at a cost of $8,000, has a record of 66 per cent. of the 80 patients cured or recovered sufficiently to leave the camp. The legislature is to be asked for $50,000 to erect new buildings for increasing the capacity from 30 to 75 patients.

Dr. Ashton Goes to the University.—Dr. Thomas G. Ashton, formerly connected with the Jefferson Medical College, has been elected adjunct professor of medicine in the University of Pennsylvania. Dr. Ashton is one of the most prominent of the younger teachers of medicine in this city. Early in the present year he was chosen Professor of Clinical Medicine in the Philadelphia Polyclinic and also a manager of the hospital of the University. He is visiting physician to several hospitals.

The Relation of Food Preservatives to the Public Health.—Dr. Victor C. Vaughan, of Ann Arbor, Mich., addressed the Pathological Society of Philadelphia, on the above subject, December 8. The discussion was opened by Dr. Charles Harrington, of Boston, and Prof. C. B. Cochran, of West Chester. Dr. Vaughan prefaced his remarks by a consideration of the general principles of food preservatives, stating that they have been used since prehistoric times. He said that in deciding whether a certain preservative or preservatives in general are to be allowed, people suffering from disease, as well as the healthy ones, are to be considered. The aged and infants are also to be remembered, especially unhealthy infants. To be legally sanctioned, preservatives must be innocuous to all these groups.

Preservatives that Do Not Preserve.—Dr. Vaughan said that many questions regarding the use of preservatives would be settled if it were decided what substances are real preservatives and what are preservatives in name only. A material put into a food to maintain a color or to impart to it another color is not a real preservative, nor is one that only prevents the appearance of a disagreeable odor a real preservative is one that prevents the growth of deleterious bacteria. In experimenting with the lactic acid bacillus he has found that formaldehyde in strength as low as 1 to 50,000 will hinder its growth in such a manner as to prevent milk souring but it has little or no effect on colon bacilli. If the latter are present in milk, the formaldhyde is a source of danger in that it may be responsible for a false sense of security. A mother would never give sour milk to a child, but if the formaldehyde prevents its souring she will give it though it contain other bacteria. This was likened to an obstructed street at night with its red lantern; the danger signal is taken down by the so-called preservative but the obstruction still remains. Sodium sulphite may be of the same order; there is need of investigation of numerous substances along this line.

Regulation of Poisonous Preservatives.—Experts differ as to what constitutes a poison but Dr. Vaughan designates as a poison any substance which chemically destroys cells or impairs their function. These substances should be permitted as preservatives only under the most careful regulation by law. Their secret use, even in quantities much below what would be considered a poisonous dose, is not permissible. Any person who chooses should not be allowed to put poisons in our daily food when physicians are the only ones allowed by law to administer poison to other individuals. Druggists and physicians are regulated by law in handling poisons; why not regulate their employment in foods? Certain poisons are good preservatives for certain foods at proper times but this must be known by all who eat those foods. The three requisites of a preservative are: (1) It must be a real preservative; (2) in comparatively large quantities it must not materially impair the digestive and allied functions; (3) it must not be a cell poison or else be added only under legislative restrictions by persons authorized to do so and the food containing it must be so labeled.

Ventilation of Railway Cars.—The Pennsylvania Railroad Company has, after a period of experimentation, adopted a device for ventilating its passenger coaches which promises to do away, not only with bad air, but also with the overheating and underheating of the cars—three evils from which every traveler has at some time or other suffered. The description of the device indicates that there is about it nothing that is severely complex. Outside air is brought into the car through hoods covered with wire gauze to exclude cinders, passed through vertical downtakes to a space under the floor, whence it is driven into the heater boxes and warmed by the

radiators. From the heater boxes the air passes into the car proper at points in the main aisle, performs its mission and is allowed to escape through the ventilators which are provided with the necessary suction to aid the circulation of air. When all the ventilators are open, 60,000 cubic feet of fresh air is provided per hour. In a day coach this would give each passenger approximately 1,000 cubic feet of fresh air, or fifteen complete changes of air every hour. In a Pullman sleeper, the amount per passenger would be much greater. There is also a method of compensating for the difference of conditions when the car is in motion and when it is not. The tests on the Pennsylvania have been so satisfactory that several hundred cars have already been equipped with the device. If all that is claimed for the system is true, its general adoption, it would seem, cannot long be delayed, for the things that it is said to accomplish are parts of a reform long needed.

CHICAGO.

Work of the Medicolegal Committee of the Chicago Medical Society.—This Committee, during the two years of its existence, has learned several facts. The first of these is that no circumstance is too trivial to form the basis of a damage suit. For example, a member of the Society is being sued at the present time on the following facts: A child of about a year had an ordinary bronchitis or bronchopneumonia. It was not especially sick. He saw it about five or seven times in a week or ten days. He was told that the child was better, and that he need not call any more. Another physician attended it for about a week. By that time the child was well. The first doctor tried to collect his bill. The parents resisted, suing him for $10,000 damages. The child is well and always has been, except for that two weeks. Another example: A doctor attended a child in 1900. He sued for his bill. The employer of the father told him that he must pay the bill or be fired, or justify himself in a refusal to pay. It costs $10 to the lawyer to start a suit, so one was started. This is 1904, nearly 1905; the man has not paid the bill, nor been fired. The second point that the Committee has learned is that it is not the wealthy, conspicuous doctor who is sued, as a rule. The Committee has found that nearly all suits are entered as a means of resisting a physician's bill in the hope of a compromise, and nulling the bill, paying the lawyer, and perhaps getting $25 or $50 for the party suing. As would be expected, they seldom go after a man unless they think he can be bluffed. A man who has large means or large influence is seldom menaced. They are especially prone to go after the younger men. The next thing the Committee noticed is that there is fashion in damage suits. A few years ago the fashion ran to fractures and dislocations. Now it runs to diseases of women and children, including the conduct of labor. The prevailing fee for obstetrical service and after-care is so very small in certain parts of the city that the physician is mentally compared with the midwife. Therefore, when he fails to devote all of his time to a case for a certain while, he is very liable to be sued for negligence. It is very apparent to the Committee that the damage suit laws should be amended. Any man, with or without apparent cause, can get another man to put up $10 for the cost of a suit. The entering of a suit and the advertising given it does some man, whose reputation in his capital, great damage, yet he has no recourse. This is the only country in the world that does not require an indemnifying bond as a condition for instituting suit.

Evidence of Impurities in Prescriptions.—The State Board of Pharmacy is about to prosecute more than one hundred druggists of Chicago for selling adulterated drugs. The evidence has been procured and chemical tests have been made which prove the presence of alien matter in the prescriptions which called for pure drugs.

Coroner's Report for the Year Ended November 30.—The total number of deaths investigated during the year was 5,960, and 3,821 inquests were held. In causes of death fire heads the list with the Iroquois loss of 575 lives. There were 426 suicides, and 382 met death in railroad accidents. Of the suicides, 103 were between forty and fifty years of age.

Insane and Paupers.—The annual report of the Detention Hospital shows that the total number of patients admitted during the year was 1,604. Superintendent Podstata, of the Dunning Institutions, reports that the improvements in the way of new buildings have been of inestimable benefit; that the farm has realized substantial revenues, and many novel features have been provided for the patients. The average daily number in the insane department has been 1,780, and at the Poor House, 1,160. The total cost of maintenance has been $376,442.

County Hospital.—Warden Happel, of the County Hospital, reports that valuable additions in the way of service and buildings have been provided. During the year 22,301 patients have been treated at the Cook County Hospital. The total cost of maintenance was $329,268.96.

Report of Chicago Lying-In Institution and Dispensary.—"Three thousand, nine hundred and ninety-nine babies, born in the homes of the poor, within seven years, without one mother's death." This is the record of which the directors, officials and obstetricians of the Chicago Lying-in Hospital and Dispensary are proud. They believe it to be unequaled in the history of maternity hospitals, the world over. This institution and dispensary was established in 1895. Since that time 5,800 cases have been cared for. During that period of nine years only three deaths have occurred. Of 700 cases treated at the hospital itself only one has been lost in spite of the fact that many desperate cases were received. In this quarter of the city from five hundred to one thousand cases should be cared for yearly, and the officials at the hospital are endeavoring to raise $12,000 for the erection of a suitable dispensary.

Work of Children's Hospital Under Consideration.—A recent announcement was made that approximately $100,000 already had been subscribed for the construction of the Children's Memorial Hospital, which will cost $300,000. As the hospital is to be built on the pavilion plan, one section at a time, it is probable that work will begin soon. The nucleus of the new institution will be the Maurice Porter Memorial Hospital for Children. Mrs. Julia F. Porter founded the institution in 1882, as a memorial to her son. Mrs. Porter will give $75,000 toward the new institution, and another gift of $20,000 is in hand, with many smaller subscriptions. An endowment in perpetuity requires $5,000; for a year, $250; and during one life, $3,000.

Reappointment of Dr. Podstata.—Dr. V. H. Podstata has been reappointed superintendent of the County Institutions at Dunning; Dr. H. I. Davis has

been appointed County Physician, and Dr. Henry G. W. Reinhardt has been appointed Assistant Coroner's Physician.

New Hospital.—The design of Richard E. Schmidt has been accepted for the new Michael Reese Hospital, which is to cost about $400,000. The new hospital will be a six-story fireproof structure.

Appointment of Dr. Howard.—Dr. Henry William Howard has been appointed Secretary to the Surgeon-General, with the rank of first lieutenant and assistant surgeon.

Rock Island System Surgical Association.—The second meeting of this Association was held in the Assembly Hall of the Northwestern University Building, December 7 and 8. There were approximately 150 railway surgeons in attendance, and papers were read and discussed as follows: "Our Association," by Dr. T. B. Bradford, Cotton Plant, Ark.; "Two Seemingly Hopeless Cases," by Dr. W. F. Fee, Meade, Kan.; "Traumatic Laceration of Urethra; Resection and Bone Suture for Ununited Fracture of Ulna and Radius," by Dr. H. A. Leipziger, Burlington, Iowa; "Burns and Scalds," by Dr. R. P. Tye, of Chickasha, I. T.; "Is the Present System of First Aid to the Injured, as Practised in the U. S. Regular Army Applicable in Railroad Work?" by Dr. F. H. Clarke, El Reno, O. T.; "Infected Wounds," by Dr. J. A. Finlayson, of Armstrong, Iowa; "First Treatment of Eye Injuries," by Dr. R. S. Magee, of Topeka, Kan.; "Embolism of the Popliteal Artery, with Report of Three Cases," by Dr. E. W. Clark, Grinnell, Iowa; "Pupil Reactions and Field of Vision in Examination of Railway Employees," by Dr. W. C. Bane, Denver, Col.; "Punctured Wounds, with Report of an Unusual Case," by Dr. C. B. Kimball, West Liberty, Iowa; "Street Railway Surgery," by Dr. A. O. Williams, Ottumwa, Iowa; "A Queer Case of Malingering," by Dr. Geo. P. Hanawalt, Des Moines, Iowa; "Injuries to the Deep Muscles of the Back, with Report of Cases," by Dr. M. W. Bacon, Englewood, Ill.; "The Local Surgeon, his Duty to the Injured and his Duty to the Railway Company," by Dr. G. A. Spaulding, Avoca, Iowa; "Hysteria: Can it be Traumatic?" by Dr. L. W. Littig, Iowa City, Iowa; "The History of the Shield Dressing for Injured Eyes," by Dr. H. Gifford, Omaha, Neb.; "The Treatment of Sciatic Rheumatism with Solution of Osmic Acid," by Dr. S. V. Hall, Rock Island, Ill.; "Extensive Necrosis of Frontal Bone Following Slight Injury," by Dr. G. E. Hartshorne, South McAlester, I. T.; "Compound Comminuted Fractures of the Leg with Reports of Three Cases," by Dr. D. I. Christopher, Colorado Springs, Col.; "Dressing Compound Fractures," by J. V. Brann, Knoxville, Iowa. Delegates were appointed to the American Association of Railroad Surgeons. In the afternoon of the second day, Professor Weller Van Hook gave a surgical clinic at the Wesley Hospital. He operated on and exhibited several interesting surgical cases, making running comments on each as to the methods pursued and after-treatment. Dr. Van Hook was tendered a rising vote of thanks for his entertaining and instructive clinic.

GENERAL.

German Birthrate.—Official statistics covering twenty-six years show a steady and noticeable decrease in the birthrate in the large cities in Germany, in spite of the fact that the marriage rate is higher than in cities of less than one hundred thousand inhabitants and in the country. Berlin, which passed the two million mark in December, presents the heaviest decrease in the birthrate. In the period from 1896 to 1900, it averaged 28.9, against 44.9 from 1875 to 1880. The highest birthrate is in the great industrial centers of the Rhenish provinces.

Proposed Memorial to Dr. Osler.—The first organized movement to consider the proposed memorial to Dr. Osler, who will leave here in June to take up his residence in England as regius professor of medicine at Oxford University, took place last week at a meeting of the Baltimore City Medical Society. The plan is to erect a library building in some suitable location in Baltimore, costing about $100,000. The sum of $10,000 has already been contributed in Baltimore, and committees have been formed in Philadelphia and Cleveland for the purpose of raising money. Dr. John H. Musser, professor of clinical medicine at the University of Pennsylvania, has consented to be chairman of the national committee now being formed. The national treasurer will be Gov. Warfield, of Maryland, and Dr. Henry Barton Jacobs will be secretary.

Dr. Osler's Successor.—It was learned last week, writes the Baltimore *Sun*, that the trustees of the Johns Hopkins University and the advisory board of the medical faculty of the institution are now strongly inclining to the appointment of Dr. Lewellys Franklin Barker, professor and head of the Department of Anatomy in the Rush Medical College of the University of Chicago, and formerly of the Johns Hopkins University, as the successor of Dr. William Osler, who leaves Baltimore next spring to become regius professor of medicine in the University of Oxford. While the name of Dr. Barker has been previously mentioned among a number of others as a probable successor to Dr. Osler, it now seems that the appointment of Dr. Barker has become the most favorable one in the eyes of the most important members of the Johns Hopkins Medical Faculty, who will virtually decide upon the final choice. It has ever been the policy of the Johns Hopkins University to endeavor to secure as the heads of departments men of extraordinary genius, without respect to age, the principal qualification being a reputation for ability in original scientific research work and investigation, and it is for this qualification that Dr. Barker commends himself so favorably to the authorities of the institution.

Although a young man, only thirty-seven years old, Dr. Barker's career has been a brilliant one, and he stands to-day among the foremost anatomists of the country, and is ranked as an authority among such prominent men as Prof. Franklin P. Mall, of the Johns Hopkins Medical School. In his course of work at the Johns Hopkins University from 1891 to 1900, during which time he held a number of positions, his work was stamped as extremely brilliant and in such investigations as his services upon the Johns Hopkins Medical Commission to the Philippines, he won the admiration of scientific men throughout the country.

Dr. Barker is a Canadian—a native of Norwich, Ont. He received much of his education at Canadian institutions and his medical degree at the University of Toronto. Dr. Barker was house officer of the Toronto General Hospital, 1890-1891, assistant physician of the Johns Hopkins Hospital 1891-1892, Fellow-in Pathology in the John Hopkins University, 1892-1894, associate in anatomy, 1894-1897, associate professor of anatomy, 1897-1899. In 1899 he was a member of the Johns Hopkins Medical Commission to the Philippines, and in 1901 a member of the special

commission appointed to determine the existence or non-existence of the plague in San Francisco. He is the author of a number of medical and anatomical treatises. While there are a number of other men suggested to succeed Dr. Osler, Dr. Barker is said to be nearer the type of scholar desired, and that he will be the favored one to be chosen. The advisory board, which virtually makes the choice, is composed of President Ira Remsen, Dr. Osler, Dr. William H. Welch, Dr. H. M. Hurd, Dr. H. S. Kelly, Dr. W. K. Brooks, Dr. W. S. Halstead, Dr. J. J. Abel, Dr. W. H. Howell, Dr. F. P. Mall and Dr. J. Whitridge Williams.

Aesculapian Club.—The Aesculapian Club, of Boston, held its winter meeting at the Medical Library, Thursday, December 8. Dr. T. C. Munro and Dr. E. H. Bradford were the guests and speakers of the evening. This Society, founded in 1902, takes in annually from the graduating class of the Harvard Medical School eighteen members, forming a new "chapter" with separate organizations and meetings. The club, as a whole, has two meetings a year. The object of the club is "to encourage in its members a spirit of emulation in medical work, and to promote a permanent active interest in the affairs of the Harvard Medical School;" in addition to this there is a social side to its meetings which render them besides instructive very enjoyable. At the last meeting Dr. Munro gave a most entertaining talk on the Mayo Brothers, of Rochester, Minn., and Dr. Bradford on "The Future of the New Harvard Medical School."

Clever "Hans" now a Telepathist or Muscle Reader.—Some time ago the fame of a horse named "Clever Hans" spread over the newspaper world. Hans spelled out names, told the time, did simple sums in arithmetic and had other attainments which caused him to be seriously credited with reasoning powers on a scale never before reached in the horse world. A scientific commission which was appointed to investigate the stories of the animal's wonderful performances has made a report in which it says that Hans is unable to count or read a sum. It was demonstrated that he was unable to answer a question unless the question was known to one of the bystanders. He was likewise unable to answer when blindfolded. The commission concludes that the horse requires optical assistance, but adds that it does not follow that the assistance must be knowingly given. The commission believes that the horse has been so perfectly trained as to be able to recognize the slightest change in bodily position, which is a natural consequence of the trainer's course of thought. One commissioner declared that the horse was able by careful watching of the owner to recognize the slightest movement which was unknown to the owner himself, the latter serving as a communicating medium to the horse's intelligence.

Boston's Great Opportunity.—That $5,500,000 of the estate of Peter Bent Brigham, who died in 1877, can be used to found a hospital in this city for indigent persons, was the decision of Judges Putnam, Aldrich and Brown in the United States Circuit Court of Appeals to-day. The money has been turned over by the Brigham executors to the Peter Bent Brigham Hospital Corporation, which was organized in pursuance of the terms of Mr. Brigham's will. Herbert F. Brigham, one of the heirs, brought a bill in equity to recover his alleged share of the vast estate, upon the ground that the gift for the hospital was void, as being in violation of the rule against perpetuities, as it was the intent of the will that the gift should vest at a time beyond the life or lives of persons living when the testator died and twenty-one years after. The plaintiff also held that the amount of the gift beyond $1,500,000 was distributable among the relatives of Mr. Brigham upon the ground that by the general laws of Massachusetts a corporation such as the hospital had no legal power to hold more than $1,500,000 in property. Mr. Brigham's will directed that the residue of his estate should be "held, managed and invested" by his executors "for the term of twenty-five years from the time of his decease." The executors were to pay certain annuities, and to add the surplus income to the principal, and at the expiration of the twenty-five years they should dispose of the fund to found a hospital in Boston, to be called the Brigham Hospital, for the care of persons in indigent circumstances.

Ohio State Sanatorium for Tuberculosis.—The Ohio State Sanatorium Commission at a recent meeting adopted the following minimum requirements for a site for the proposed hospital for tuberculosis: (1) It shall include not less than 350 acres of land. (2) A portion of this land shall be not less than 800 feet above sea level. (3) A certain part of it must be timbered. (4) The land must afford a suitable site for buildings, sloping south, south-southeast or south-southwest; and be well sheltered from prevailing winter winds. It must also offer a pleasing landscape. (5) The soil must be dry, pure, easily drained, and at least 100 acres shall have good agricultural qualities. (6) An abundant supply of pure water shall be easily accessible. (7) The site must be not more than three miles from a railway station, and not less than one mile from any city or village. (8) It must afford good railroad facilities and be easily accessible from any part of the State. The chart on preceding page is taken from the report of the State Tuberculosis Commission, published the first of the year. This shows roughly the sections of Ohio that are over and those below 1,000 feet in elevation, and in addition some of the small areas that are above 1,200 feet. Less than one square mile is over 1,500 feet above sea-level. This is in west-central Logan County, near Bellefontaine, where one hill rises to 1,540 feet and another to 1,525 feet. At least one-fourth of the State is above 1,000 feet. Of this it is estimated that about 4,000 square miles is in the western half and the balance in the eastern. There are extensive areas in the eastern section rising from 1,200 to 1,300 feet above sea-level. The area of the State is 40,760 square miles, and it is estimated that only 460 square miles is below 500 feet. The lowest point is about 425 feet above mean tide. The mean elevation is probably slightly above 850 feet.

Needs of the Naval Medical Corps.—It appears from the report of Secretary Morton that the Medical Corps of the navy is the only branch of the service in which there are vacancies at the foot of the list comments the New York *Sun*. These have existed for some time, and how to fill them is a difficult problem. There are plenty of applicants for appointments, but their general quality is not what is desired, as is shown by the facts that of ninety-seven physicians who sought admission to the navy last year only twenty-three received commissions as assistant surgeons. The standard set is high. To qualify for the examinations the candidates must not only be graduates of a high-grade medical school, but must have had one year of professional work. But even those who fill these re-

quirements, while equipped for ordinary practice, have, as a rule, no knowledge of the special problems with which they are likely to be confronted in the service. To overcome this difficulty a naval medical school was established three years ago, which gives a six months' course and turns out men well fitted for active duty. Last March it graduated thirty officers and twenty-four are now under instruction. The increasing number of vessels in the navy has increased the demands on the Medical Corps. The difficulty of securing good men is not a new one and from year to year there has been much talk of a remedy, but nothing effective has been done. Surgeon-General Rixey, in his report for the year, emphasizes the needs of his corps and devotes much space to a discussion of its unfilled list. He says that the board of examiners has sat almost continuously, lectures on the naval service have been delivered in the leading schools—in fact, everything possible has been done to get enough high-class men to fill the vacancies, and still the men are needed. "It was thought," says Dr. Rixey, "that the favorable legislation of 1903, giving rank of grade and increasing the number of surgeons and establishing a closer parallelism between the army and navy medical establishments, would so serve to popularize the naval medical service among qualified young professional men as to make recruiting for it an easy matter." But here, too, were disappointing results. The Army Medical Corps is full and continues to draw to it an excellent class of candidates. So it is with the Marine Hospital Service. The medical journals explain this partly by pointing out that the pay of an assistant surgeon of the navy when ashore is 15 per cent. less than that of an assistant surgeon of the army. Again, it is insinuated that the line of the navy has not entirely lived down its old reputation for treating the medical officers ungraciously; that while this reputation is unwarranted, it still exists and exercises a repellant influence. The wars of the last few years, with the one now being waged in Manchuria, have peculiarly emphasized the necessity of the most efficient possible medical corps in both branches of the service, and Congress should by legislation support the efforts of the Secretary and Surgeon-General to secure for the navy a full and efficient medical staff.

Boston Medical Library Society.—The third of the Boston Medical Library meetings held in conjunction with the Suffolk District Branch of the Massachusetts Medical Society, was held Wednesday evening, December 7, at the Library. The subject for discussion was "The Humane Treatment of Malignant Disease from a Surgical Point of View." The paper of the evening was given by Dr. John C. Munro. Dr. Munro made an earnest and eloquent appeal to the medical man and to the general practitioner to get in a surgeon earlier than heretofore before it was too late, and to allow the patient some choice at least in the matter of an operation, whether or not an absolute cure were possible. What might have happened without an operation can never be told but there was always the possibility of making a wrong diagnosis, no matter what the signs were, and a condition no matter how hopelessly malignant it appears, might prove to be benign and quite capable of cure. Case after case was cited to show this, where an apparently hopeless operation had been done merely to alleviate pain and a benign condition found. He maintained that until diagnosis of incurable malignant disease could be definitely and surely made it was safer to operate, after, of course, all other means had been exhausted. To operate when there was a chance to cure the patient without one, he said, was wrong; but to oppose an operation and to allow the patient to die when there was a $^1/_{1000}$ chance of cure was far worse. He next spoke on operations to alleviate suffering, citing cases not of cure but of a happy and comfortable existence for months and years afterward, the patient finally dying of a general toxemia and not of some painful local process. All cases were not fulminating ones, and it was possible to tell to what extent relief might be given. He dwelt especially on the added mental comfort to the patient after an operation and asked why, if all external tumors are immediately handed over to the surgeon, internal ones as well should not be, especially as now in experienced hands the dangers of a laparotomy were so slight.

Dr. R. H. Fitz spoke confining himself to malignant diseases of the stomach. His paper was brief being composed largely of statistics from an article recently published by Dr. Munro, in which the speaker showed that the mortality on so-called exploratory operations of the stomach was very high indeed.

Dr. David Cheever, while admitting that only in rare cases of operating on advanced malignant disease is a cure possible, yet the mental effect on the patient and the relief of suffering makes such operations desirable.

Dr. A. T. Cabot thought that a certain amount of danger to the patient's life was quite justifiable if there was a chance, however small, of marked relief or cure.

Dr. Fred. Lund cited cases illustrative of this same subject in which, while there was no cure, yet there was a very great relief from pain.

Dr. Francis Williams spoke of X-ray treatment as a palliative measure and explained a new device whereby by means of special tubes and plates of aluminum treatment could be given to far deeper growths than possible at present without danger of severe burns.

Dr. H. L. Burrill spoke of the indefiniteness of the term "malignant." He advised leaving the diagnosis to the surgeon if there was any chance of doubt.

Dr. F. B. Harrington thought an early operation really cured in more cases than generally thought and that, owing to the spreading abroad of this fact patients were coming in for treatment much earlier than formerly.

Panama Canal Service.—The United States Civil Service Commission announces an examination on January 18, 1905, to be held in the chief cities of the United States, to secure eligibles from which to make certification to fill vacancies in the following-named positions under the Isthmian Canal Commission on the Isthmus of Panama: Surgeon, physician, pharmacist, hospital interne, trained nurse. The scope and character of these examinations are as indicated below. Each applicant for the Isthmian Canal Service will be required to submit to the examiner, on the day he is examined, a recent photograph, not more than three years old, of himself, which will be filed with his examination papers, as a means of identification in case he receives an appointment. An unmounted photograph is preferred. The date, place, and kind of examination, the examination number, the competitor's name, and the year in which the photograph was taken should be indicated on the photograph. For further information concerning transportation to the Isthmus, conditions

of employment, etc., attention is called to Form No. 1417, obtainable on application.

Surgeons.—Age limit, twenty-five to fifty years; salary, $250 per month. The examination will consist of the subjects given, with the relative weights indicated: (1) Anatomy, 5; (2) surgical bacteriology, 5; (3) surgical pathology and diagnosis, 15; (4) surgical practice, 40; (5) surgical gynecology, 5; (6) practical experience (this element will be rated upon the statements made in the application and accompanying vouchers. Special attention will be given to the quality of the applicant's experience, and applicants who have had extensive work in large hospitals will receive special credit), 30.

It is the desire of the Isthmian Canal Commission to appoint in this position only surgeons of thorough training and wide professional experience.

Physician.—Age limit, twenty-five to fifty years; salaries, $150, $200, and $250 per month. The examination will consist of the subjects given below, with the relative weights indicated: (1) Letter-writing, 5; (2) anatomy, 5; (3) therapeutics, 5; (4) physical diagnosis (including questions relating to tropical disease), 25; (5) general pathology and practice (including questions relating to tropical diseases), 25; (6) bacteriology and hygiene, 5; (7) obstetrics and gynecology, 5; (8) practical experience, 25. The element of practical experience will be rated upon the statements made in the application and accompanying vouchers. Special attention will be given to the quality of the applicant's experience, and applicants who have had experience in hospitals, particularly in the treatment of tropical diseases, will receive special credit. Only those who have had extensive hospital experience and are familiar with the treatment of tropical diseases, will be selected for appointmnt to the highest salaried positions. Promotions may be made in the discretion of the Isthmian Canal Commission from the lower to the higher positions in this grade.

OBITUARY.

Dr. J. F. Fischer, a native of England and a Civil War veteran, was found dead in his bathrom, at his residence on Ridge avenue, Philadelphia, on December 9. He was sixty years old and enjoyed a lucrative practice until his health failed two years ago. He was graduated from Jefferson Medical College in 1872.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, November 26.

GENERAL MEDICAL COUNCIL—BRITISH SOCIETY AND GERMAN SURGEONS—ASEPSIS IN THE BARBER'S SHOP—A MEDICAL COLLECTOR'S LIBRARY—DEATH OF A COURT PHYSICIAN—AN ABSENT-MINDED PRESIDENT—AN ECHO OF THE VISIT OF FRENCH DOCTORS.

The General Council of Medical Education and Registration, which is our professional Parliament, is now holding its eightieth session. The most important part of the proceedings was the announcement by Sir William Turner, Principal of the University of Edinburgh, that he had made up his mind to resign the office of President of the Council which he had held for about six years. The reason assigned for this step is that his duties in Edinburgh are of an onerous and absorbing nature and have their first call on his time and energy. For some months past he has become conscious of the fact that, having entered upon the stage of life which entitles one to be called a septuagenarian, the vital mechanism cannot be driven at the speed, and with the continuity of effort, which was both possible and pleasurable a few years ago. The President would have done better to follow the wise counsel offered to a newly appointed judge, whose knowledge of the law was imperfect, to give his decisions without stating the reasons on which they were based. Sir William Turner's decision does him credit, but the reasons assigned for it make one wonder why it never occurred to him until lately that duties, which ought to have been still more onerous and absorbing than the largely ornamental functions of Principal, were incompatible with those of the office which he is about to resign. When he was elected President of the General Medical Council it was understood that he would resign the chair of anatomy at Edinburgh which he had occupied for many years. Indeed, the fact that he was the incumbent of that chair was held to be an objection to his being put forward for the presidency, and it was only on the understanding referred to that the objection was waived. On his election, however, it became manifest that the "understanding" was in fact, as such things often are, a misunderstanding, and Sir William continued for some time to hold both offices. The explanation given by his friends was that he wished to complete the term of office as professor that would entitle him to a retiring pension. This did not altogether satisfy the objectors, but they had to accept the situation. By the way of making a graceful exit the President has presented a handsome silver gilt mace to the Council. Though he retires from the presidential chair he will continue to be a member of the Council till the end of 1906. He has been a strong President, if not exactly a great one.

A good deal of suppressed indignation is felt among the medical profession here at the removal of Mrs. Arthur Paget, a particular friend of the King, to Berlin for treatment by a German surgeon. In August last the lady fell down the lift in her own house with the result that both her legs were broken. The right was fractured in three places, at one of which union failed to take place. A short time ago Sir Frederick Treves visited her by command of the King. It was proposed to wait for some time and then wire the fragments. Apparently, however, the patient was not altogether pleased with the prospect, for the aid of Professor Hoffa, of Berlin, was invoked. He is said to have "put the broken bones together in two hours while the patient was under chloroform." Mrs. Paget has now gone to Berlin to be under his treatment. The case is boomed somewhat in the daily newspapers as a triumph of "bloodless surgery," and Professor Hoffa himself is described as "a German bonesetter." Evidently it is this "bonesetting" reputation that makes English Society believe in him; when they find out that he is only a scientific surgeon and a genuine professor in the Medical Faculty of a great university, they will probably lose faith in his thaumaturgic powers. The British profession does not grudge Hoffa his reputation as a "bonesetter," but our surgeons are not unnaturally somewhat nettled that it should have been thought necessary to take the patient to Germany. It is by no means a solitary instance. The members of the "upper ten," and those who

wish to be thought to belong to that class, flock to Pagenstecher when they have anything the matter with their eyes. The fact is that the fashion has been set by the Court which has an unpatriotic preference for German doctors. The Princess Christian loses no opportunity of sounding the praise of Pagenstecher and other Germans, and Society follows her like the little lamb that went after Mary in the nursery rhyme. She got Pagenstecher to see Queen Victoria; but, to prevent an outcry, he was ushered in by the backstairs. There are two Germans on the small committee appointed by the King to organize the sanatorium which is to be built and the money supplied by Sir E. Cassel, another German; and the physician selected by the committee for the post of Medical Director of the institution is a German. Altogether it is felt that in the sphere of medicine our Royal Family, in accent as in other ways, is more German than English.

The public Health Department of the Corporation of the City of London, after careful consideration of the dangers of septic shaving, has, in conjunction with the Incorporated Guild of Hairdressers, strongly urged the City Fathers to regulate the sanitary conditions of barbers' shops. The following proposals have been laid before them: (1) All shelves, fittings and tables on which instruments are placed to be of glass, marble, slate or other similar material. (2) Clean towels, etc., to be used for each customer, and a fresh piece of paper or clean linen to be placed on the back of chair or head-rest. (3) No general powder-puffs to be used, and powder pulverizers or cottonwool substituted. No sponges to be used. (4) All hairclippers, razors, scissors, combs, or other tools, after use, to be placed in a disinfecting solution. (5) Razors to be wiped on paper. (6) Perfect, clean hairbrushes only must be used. (7) Shaving brushes after use to be placed in a disinfecting solution. (8) Cut hair falling on the floor to be immediately swept up and removed and floors to be cleansed daily. (9) No general styptics, as alum crystals or blocks to be used, nor powders nor liquids applied on a towel or cottonwool, or by spray. (10) The most scrupulous cleanliness to be observed in all that pertains to the business.

In addition it is recommended that regular customers should be strongly advised to provide their own toilet articles—razors, brushes, etc.—which would be exclusively reserved for their owner's use; that all cut hair and paper should be burned; and that no customer apparently suffering from any skin or hair affection should be attended to save at his own house or offices, or in a private room. A further proposition provides for registration. This means that all barbers complying with these regulations will have a certificate to the effect that they are "fit and proper persons" to undertake the removal of superfluous hair with safety to the customer. Dr. Collingridge, the medical officer of health of the City of London, says disease is spread to a large extent through the "penny shaves," and it is to control these that the movement has been initiated.

The late Professor W. H. Corfield was best known to his professional brethren throughout the world as a leading sanitarian. To a smaller circle he was known as an enthusiastic collector of books, and especially as a connoisseur of bindings. To any one interested in his "hobby" he was always pleased to show his treasures, and he was a most interesting *cicerone* for, unlike many bibliomaniacs, he knew the inside as well as the outside of his books. He would even lend them for months together to a friend who wished to use them for literary purposes—surely a stretch of liberality almost unheard of in a collector. Part of his library was sold a few months ago for $3,500. The choicest part of the collection has been disposed of this week and brought over $25,000. It is considered doubtful by experts whether any other private collection comprised so remarkable a series of English bindings. Each book in Dr. Corfield's library was selected to exemplify in some way or another the art, workmanship, or development of bookbinding, and many of the volumes were in the Burlington Fine Arts Club Exhibition of 1891. Dr. Corfield was one of the few collectors who made a specialty of bindings, and many of the books which have just been sold realized far more than they cost him. In one instance, a volume, acquired at an auction sale for $25, realized $630. This is an extreme instance, but on the whole a very handsome profit has resulted from the doctor's "hobby."

Dr. G. Vivian Poore, who died a few days ago at the age of sixty-one years, was for some years the physician and the trusted friend of the King's younger brother, the late Duke of Albany. The Prince was a "bleeder" and required constant medical supervision. The late Sir William Jenner's life was for some time made a burden to him by incessant calls to attend the royal patient, who could hardly move without hemorrhage taking place into a joint. Jenner handed the Prince over to Poore who thus got an introduction to the Court which afterward stood him in good stead. Poore was a man of polished manners and an excellent all-round physician. He dabbled in several specialties—electricity, laryngology, neurology, and forensic medicine, and wrote more or less valuable treatises on all of them. He was emeritus professor of medicine in University College, and physician to the hospital attached thereto. As a sanitarian he was something of a heretic on some points. He would denounce cremation, not on religious but on scientific grounds, as a wanton destruction of the best natural manure. He had strong opinions as to the disposal of human excreta, which he held should always be applied to the fertilization of the soil. He had a garden in the suburbs in which he grew very fine vegetables by this method, and he claimed to get marvelous results from the same system on a small estate which he possessed in Hampshire. He was a charming man with whom even the most aggressive and self-assertive of colleagues must have found it difficult to quarrel; this was not due to any weak amiability in Poore but rather to a genial cynicism which prevented his taking himself or any one else too seriously. All Poore's writings are marked by sound practical sense and withal are eminently readable.

In a new edition of the letters of Thomas Gray, poet and naturalist, which is now in course of publication, a curious story is told of the absent-mindedness of a former President of the College of Physicians, by which that institution lost a great public trust that would have given it a much higher position in the public eye than it now holds. It appears to be only by accident that the great anatomical, pathological and zoological collection gathered by John Hunter, which formed the basis of the famous Hunterian Museum of the Royal College of Surgeons of England, came to be under the con-

trol of that body. By his will Hunter directed that his collection should first be offered to the British Government on reasonable terms; if it declined to buy—and it was a time when British Ministers thought far more of cannon than of scientific collections—the museum was to be offered to some foreign State or otherwise sold in one lot. With some difficulty the British Government was induced to purchase the collection for $75,000. It is said in the publication mentioned above that the Government invited the Royal College of Physicians to be the conservators of the collection. The offer was made through Dr. Thomas Gisborne, at that time President of the College, who put the letter conveying the proposal into his pocket and forgot all about the matter. After a time the Government, concluding that the College of Physicians did not wish to have anything to do with Hunter's specimen's, transferred the offer to the College of Surgeons which at once accepted the trust. Its enterprise has been largely rewarded. Without its Museum the dingy institution in Lincoln's Inn Fields would be nothing but a not particulary high class diploma shop.

The following incident is said to have occurred in one of the largest of our hospitals during the recent visit of the French doctors. A probationary nurse, hearing one of the gentlemen discoursing French very fluently, went up to him and rattled off an eloquent description of the most notable features of the hospital. "Most interesting, nurse! But I speak English too, as I am the Senior Surgeon of this hospital."

SOCIETY PROCEEDINGS.

CHICAGO ORTHOPEDIC SOCIETY.

Regular Meeting, held October 25, 1904.

The President, Arthur B. Hosmer, M.D., in the Chair.

Case for Diagnosis.—Dr. M. L. Harris showed a little girl, five years of age, who, when about two years of age, was taken sick. She had been well and healthy up to that time. According to the mother's statement, the child was quite sick, and remained in bed for several weeks. This was as much of the history of the case as he could elicit from the parents. There were no local symptoms about the knees, nor anything to call the attention of either parents or physicians to them. While the child was in bed the legs were gradually flexed, and when she recovered from her sickness the knees remained sharply flexed. No effort was made to extend them. Nothing was done to the legs while the child was in bed. No effort was made by the parents to extend the knees until about six months ago, when the child was brought to the city from the country and admitted to the Children's Hospital. The child was well in every way when she came to the hospital, with the exception that both legs were very sharply flexed beyond a right angle. There was no tenderness about the knees; there was no paralysis about the legs; no paralysis about the feet. The calves are all right, also the thighs. There was a little range of motion in the knees, but they could not be extended. There was apparently an enlargement of the lower ends of the femora. He put the child in bed, and extension was made in two directions. He made a trough-splint, fitted it upon the posterior surface of the leg, and attached a cord to each end and over a pulley so as to draw directly against the entire extent of the leg posteriorly, with extension also in the direction of the leg. He made quite rapid progress up to a certain point, when further extension ceased to make any improvement. Then he used force to complete the extension and applied casts. He was unable to extend the knees fully by force. After the application of force two or three times, gaining some each time, he used Ryerson's genuclast, and under anesthesia was able to get almost complete extension. This was done about four weeks ago. The legs were kept in casts until this morning. He thought the child would get motion in the knees, sooner or later. He bent them this morning far back, but it caused considerable pain. The question arises, what was the trouble with the child in the first place? Was it disease affecting the knees, or were the knees drawn up simply from the position in bed? Another question which arises is, whether in limbs so sharply flexed for so long a time the lower ends of the femora enlarge out of proportion to the rest of the bone? There does not seem now, nor has there been, any trouble with the knees. The question of enlargment of the bone, when pressure is removed, is a disputed one. If we were to amputate at the knee, the lower end of the femur would not enlarge out of proportion to the rest of the bone. The author stated that the case was not one of poliomyelitis, as there had never been any paralysis of the quadriceps muscles. There was no evidence of spastic paralysis. Dr. Harris believes the inability to extend the legs is due to the condition of the soft parts. He does not think it is due to the condition of the soft parts. He does not think it is due to contraction, but to failure of development of the soft parts, particularly the lateral and posterior portions of the capsule. When the leg is flexed, the attachments of these portions of the capsule are approximated, remaining in that position for some time until in the process of development they simply fail to develop and offer an obstacle to extension. The lower end of the left femur is larger than it ought to be, but whether there is a disproportion in size as compared with the upper end of the tibia he did not know. If there was, it must be due to the fact that it has enlarged for want of pressure. He could not see any other reason for it. It was difficult to say whether it is enlarged or not. He did not think this enlargement was the main obstacle to extension, but the failure of development of the soft parts. He looked upon the case as one of postural disease or postural deformity primarily while the child was sick, and after she was well no attempt was made to extend the knees to the natural position.

Extensive Osteomyelitis of Femur Healed Without Operation.—Dr. Frederick Cleveland Test showed an interesting case of extensive osteomyelitis of the femur that had healed without operation. The patient, fifty-two years of age, a physician, had been for the greater part of his life an athletic man. He had had the usual diseases of childhood and adolescence, yet in spite of these indulged a great deal in athletics. Twenty-one years ago, in the Schwatka Expedition to Alaska, he was one of some forty-nine, out of the party of sixty-three, who had the scurvy. During the attack, which lasted ten months, patient was run down and covered with ulcers, which persisted for nearly a year. Following this he gave up his medical work almost entirely, and devoted himself to exploring, as a

naturalist and geographer. This exposed him to a great many vicissitudes. He had two or three attacks of malaria; he had dengue; he had yellow fever. These diseases were mentioned because many of them, if not all, are what might be called blood diseases. At any rate, the blood is affected in all of them. Following the scurvy he had pyorrhea alveolaris, which still persists, but is less marked than it has been in previous years. About six and a half years ago he was in the prime of manhood, weighing about 180 pounds, at which time he fell and struck his right knee. In the course of a few hours the knee became very much swollen, tender and painful. Eventually, it measured twenty-eight inches in circumference. The patient was seen by several practitioners in New York and Philadelphia, among them Drs. Bull and Abbe. Dr. Abbe had even appointed a day for amputating the leg. The patient was also seen by Dr. W. W. Keen, Dr. J. William White, and the late Dr. de Schweinitz, of Washington. The diagnoses varied from syphilitic infection (of which there is no history obtainable) to osteomyelitis, and one practitioner made a diagnosis of tuberculosis. The leg remained swollen, although not discharging, yet evidently full of pus, for about two and a half years, when, after a slight injury, it opened and for four years discharged copiously. At one time there were twenty-two sinuses. When Dr. Test saw the case professionally, for the first time, in the latter part of last February, there were eighteen discharging openings, some of which were sinuses from the bone, and others ulcers on the surface. Patient consulted the speaker, not so much for the condition of his leg, which he deemed incurable, as for a distressing dyspnea, which for months had been affecting him. This interfered with his comfort more than anything else. The leg was discharging so that during the day, in spite of copious dressings of cotton and gauze, it would frequently almost fill the shoe, even though it were dressed twice a day. Within a few days he gave the patient extract of bone marrow, after having made a diagnosis of apparent osteomyelitis. The bone marrow was given in the hope of having a double effect, one of helping the bone to regain its normal condition, and the other of building up the much depleted blood. At that time the hemoglobin percentage was under 55. The hemoglobin soon increased rapidly. The patient had a considerable amount of cough, with a great deal of mucous râles. No tubercle bacilli were found present in the sputum. There was considerable dulness over the left side, which was attributed by some of the consultants to empyema. Personally, he thought it was an enlarged spleen. The leg began to improve. The local treatment he gave the leg was hydrogen peroxide, and in addition he applied one of the organic stearates, prepared for him by a chemical acquaintance in the University of Chicago. The stearate was made up from one of the phenyl group, and it acted in this case wonderfully. He thought the extract of bone marrow given internally was what gave the leg its impetus toward healing, although the stearate undoubtedly had much to do with it. After four months from the time of beginning of treatment the leg was practically entirely well. The dyspnea, however, continued to grow worse.

Patient was seen by several internists in this city, and with one exception their diagnosis was that of probable pulmonary tuberculosis, which the clinical condition seemed to bear out, and upon which theory they explained the dyspnea. Dr. Test's own final theory was that of a neuritis of the pneumogastric nerve produced by the long-continued sepsis, because this nerve was inhibitory, and the man's respirations were greatly increased. Furthermore, it supplies the inferior constrictor of the pharynx, and as the pharynx at that time had spasmodic contractions, its innervation was unquestionably interfered with. One consultant, who made a diagnosis more nearly like that of Dr. Test, said that in his opinion there was no pulmonary tuberculosis present, but that the trouble was probably due to some neoplasm of septic origin in the mediastinum, pressing upon the nerves there, and particularly upon the pneumogastric, and therefore advised the use of iodides. Iodides were employed, but no marked improvement seemed to result, although the patient was easier under their administration. The dyspnea rapidly increased until the patient was breathing sixty or seventy times a minute, and unable to take more than two or three steps at a time. He went to bed, and was semi-delirious for two weeks, during the end of which time Dr. Test began the use of hypodermic injections of nitrate of strychnine, in doses of one-thirtieth of a grain, twice a day, as a last resort, acting on the theory that it was a neuritis. To his delight the patient began to improve from the first day, certainly inside of the first three or four days, until, in about two months, the leg having healed meantime, his dyspnea was entirely relieved, so that now he is once more practically a well man.

NEW YORK OBSTETRICAL SOCIETY.

Stated Meeting, held October 11, 1904.

The President, G. W. Jarman, M.D., in the Chair.

Three Ovarian Cysts with Twisted Pedicles—Two Complicating Pregnancy; Two with Intestinal Obstruction.—Dr. A. Brothers presented the following tumors: (1) A cystic tumor that he had removed from a multipara, twenty-seven years of age, whose menstruation had stopped three and one-half months ago. There had been bleeding for three weeks prior to her admission to the hospital; with some pain in the inguinal regions. An unsuccessful attempt was made to prevent an abortion which occurred one week later. While making an examination under anesthesia two weeks afterward, and immediately before a contemplated trachelorrhaphy a cystic tumor in the right side of the pelvis of about the size of a full term fetus, was discovered. Immediate laparatomy showed the presence of a parovarian cyst, the pedicle of which had undergone 3½ twists. The tumor, though situated in the right side, was found to rise from the left appendage. There were no evidences of disturbed circulation. (2) The second tumor was removed from a single girl, twenty years of age, whose menstruation had stopped. The presence of a suprapubic tumor had excited suspicions of a possible pregnancy, although it was finally fairly excluded from the absence of other symptoms. After a short period of observation, symptoms of intestinal obstruction appeared, which were relieved by rectal enemata. A cystic tumor could now be definitely outlined, the pedicle of which was probably twisted. Its removal was postponed for a few days on account of a calomel stomatitis. The operation revealed a parovarian tumor of the size of a cocoanut, situated in the right side of the pelvis. Its surface was black, and its pedicle, consiting of the broad ligament, presented a

twist of 180 degrees. There were evidences of a recent peritonitis. (3) The third specimen was removed from a multipara, twenty-six years of age, who in February, 1904, had an attack of right lumbar pain that suggested renal colic complicating an early pregnancy. Menstruation did not stop entirely until after May. In August, while away in the country, severe symptoms of intestinal obstruction appeared, which were not relieved by medication for four days. She was then sent to New York and a diagnosis of peritonitis, intestinal obstruction and full term pregnancy was made. Enemata relieved the intestinal obstruction the first night she was at the hospital. A few days later, because of persistent pain, labor was induced after forty-eight hours by use of a Barnes bag, and a four months' decomposed fetus was removed. A large cystic tumor could now be felt in the right side of the abdomen. Three weeks later a laparotomy revealed a large ovarian cyst weighing three kilos that was adherent to intestines, omentum and appendix. The pedicle, which also ran over to the left uterine horn, showed a twist of more than 360 degrees with signs of beginning spontaneous amputation. The appendix, which was thickened and showed inflammatory changes at its tip, was removed. The ovary of the other side, which was enlarged, was also removed.

Dr. Joseph Brettauer, in the discussion, said that these cases are of rather frequent occurrence, and if they happen to be on the right side, are often mistaken for acute appendicitis.

Dr. J. Riddle Goffe thought that the description of the third case and the microscopical appearance of the specimen did not justify the removal of the second ovary.

Dr. J. N. West, who was present at the operation, stated the ovary was three or four times the size of a normal one, and, in view of the fact that ovarian cysts so often develop from apparently healthy ovaries, when there is a cyst of the other side, he thought its removal was a wise procedure.

Dr. H. N. Vineberg recalled two patients in his service at Mount Sinai Hospital, who had been admitted to the medical division with a diagnosis of acute obstruction of the bowels. They were recognized by the house physician, who had already served on the gynecological division, as typical cases of ovarian cysts with twisted pedicles. Acute obstruction seems to be a common symptom of this condition.

Dr. A. M. Jacobus stated that he had seen a number of ovarian cysts with twisted pedicles. Two were large dermoids; one of which had been diagnosticated as a malignant tumor of either the caput coli or the omentum; the other as a pregnancy. He had seen both of these cases before the twist occurred, and the twisting had been followed by a distinct diminution in the tension of the tumor in each case. Both occurred in single women, and one gave a history of amenorrhea. The tumors were centrally located, giving the sensation of ballottement and thus simulating a pregnancy of about five months.

Dr. E. B. Cragin wished to call attention to the likelihood of the pedicle assuming a twist after delivery in a case where such a tumor complicates pregnancy. He had seen such cases at Sloane, in which as the uterus involuted and the cyst had more room, a twist of the pedicle occurred.

Eclampsia in New-Born Twins.—Dr. Joseph Brettauer narrated the history of a case of intrapartum eclampsia, occurring in a patient, forty years of age, who had three difficult labors because of a contracted pelvis. The pregnancies and childbeds had been normal. A severe eclamptic seizure occurred without premonitory symptoms, followed in two hours by another. Coma followed with deep cyanosis and a tense pulse: rate 140. The urine was scanty, loaded with albumin, hyaline and granular casts. The irregular shape and large size of the abdomen suggested twins but only one fetal heart could be heard and palpation showed no other signs of a twin pregnancy. The cervix, which admitted three fingers, was manually dilated and the forceps easily accomplished the delivery of a deeply asphyxiated child in the L.O.A. position. A few minutes later another child presented by the breech and was also asphyxiated when delivered. Both children, after long and vigorous efforts, were resuscitated, although the breathing of the second one was always superficial. Six hours after delivery the first child had a severe and typical eclamptic seizure, which was followed during the next ten hours by four others of less severity. During the intervals the child breathed well, and showed no other symptoms. It took nourishment that was administered with a dropper twenty-four hours after birth without vomiting. The second had to be constantly watched from the moment of birth, as its respirations remained very superficial, and at times would altogether cease, so that artificial respiration had to be practised. Eight hours after delivery a mild but typical convulsion occurred, which was followed by nine others at intervals from fifteen to thirty minutes. After the last one it died. The mother had no more convulsions, but consciousness did not return, nor did the urine show any marked improvement, until three days had elapsed. The first child was then put to the breast and both mother and child progressed satisfactorily. Dr. Brettauer reported this case in order to elicit discussion as to the frequency of the occurrence of eclampsia in the newly-born of eclamptic mothers, as this, the first such case in his own experience. Although the head of the second child was not opened, he did not hesitate to exclude the possibility of an intracranial hemorrhage as the cause of the convulsions.

Dr. E. B. Cragin, in the discussion, said that in every large maternity hospital cases of eclampsia in the child, both ante and post partum, occasionally occur. Last year, at the Sloane, one child had an eclamptic seizure before delivery, as was shown by the contractures of the child, which was stillborn, and he was able to recall at least two others in which seizures occurred subsequently.

Dr. Geo. L. Broadhead's experience was similar to Dr. Cragin's. He thought that even if the head in the second child of Dr. Brettauer's case had been opened no light would have been thrown upon the case, as an intense and extensive congestion of the brain and meninges is a lesion common alike to asphyxia and death from convulsions. These children were certainly susceptible to the toxic influence of the maternal blood and the probabilities are that the convulsions were of eclamptic origin.

Dr. William S. Stone reported a case of eclampsia, occurring in a single girl, whose child breathed a few times during the extraction of the after-coming head and then succumbed. The autopsy showed a marked hemorrhage in the peritoneal cavity, which had come from a rupture of the liver. Sections of the liver showed those typical areas of necrosis that are now beginning to be recognized as the important lesions of eclampsia. He would corroborate Dr. Cragin's statement as to the frequency of such symptoms and lesions in children born of eclamptic mothers. He could recall other cases in which, although convulsions did not occur, marked jaundice was present.

Dr. J. Clifton Edgar said that in some of these cases

the mother may not be distinctly eclamptic, but may show symptoms of toxemia. He had seen one case with Dr. Jacobi, who thought the repeated convulsions were due to a cerebral hemorrhage, but complete recovery occurred and no after-effects on the musculature or ocular symptoms were left. Another child, apparently well when born, developed a severe coma in forty-eight hours. After repeated irrigations of the colon the symptoms disappeared and a final diagnosis of toxemia was made. In neither of these cases were the mothers eclamptic. One of them had been careless about her diet during the pregnancy and the urine contained albumin. The other case had jaundice and headache.

Congenital Atresia Hymenalis.—Dr. J. Riddle Goffe reported the following two cases of this condition: *Case I.*—A colored girl, nineteen years of age, had a distention of both the uterus and vagina from the repeated discharge of menstrual blood. The cornu of the uterus was involved to such an extent that by inverting the thin and flabby fundus, so that it presented at the vulva, the openings of the tubes could be distinctly seen, and were patulous for some little distance.

Case II.—A single girl, twenty-one years of age, had never menstruated, but had always been well and strong with the exception of periodic attacks of pain and discomfort since she was thirteen years of age. For the first three or four years these attacks occurred every four to six weeks, lasting a week, and were at times severe, accompanied by dizziness and spots before the eyes. They have been less severe and regular during the past four years, but every month she has suffered from malaise and headaches. She was well-developed with well-formed breasts. The lower abdomen was enlarged in the median line and a rounded mass presented the labia minora, which proved to be an imperfect hymen, bulging from the pressure of retained fluids. By rectum the vagina was found to be distended in all directions, so that it practically filled the pelvis up to the sacral promontory. An irregular summit of this tumor represented the uterus. The patient, by straining put the bulging tumor on the stretch so that without anesthesia a knife was plunged into one side and withdrawn so as to cut the hymen transversely, without causing much pain or hemorrhage. About a quart of dark, grumous blood, not coagulated and odorless, spurted out. Digital examination showed that at the upper end of the overdistended vagina, the cervix was also dilated almost to the diameter of the vagina, forming a sort of ring or band around its circumference. The canal of the uterine body was also dilated so that its wall was as thin as that of the vagina. No opening into the tubes could be appreciated by the finger. The entire cavity was irrigated with bichloride and salt solution and the patient discharged with instructions to use no douches, but to keep the external genitals scrupulously clean. These two cases of hematocolpos and hematometra suggest the problems that arise in the study of the formation of the vagina and hymeneal membrane. Ballantyne suggests the extreme probability that many of these cases are really examples of atresia of the vagina, from some of the records in which the presence of hymeneal membrane was hidden by the projecting vaginal sac. The toughness of the membrane in the second case suggested this condition, but no duplicate membrane could be found. A modification of the usual definition of menstruation as a bloody discharge from vagina, is suggested by such cases, as all of the essential factors in the menstrual function occurred without elimination from the body of its useless products. Howard Kelly calls this apparent amenorrhea, amenorrhea paradoxica.

Dr. E. C. Savidge, in the discussion, asked if the capacity of the vagina and the uterus had been enough to accommodate all the output of the repeated menstruations, or did the patient give a history of nosebleeds? He had seen a similar condition in which the patient bled regularly from the nose, although the atresia had been relieved. The uterus, however, is small and amenorrhea is still present. Such cases seem to answer the question, whether menstruation is the relief of a systemic or local condition.

Dr. H. N. Vineberg presented a drawing made from a patient, twenty years of age, who had never menstruated, but had had no symptoms. Two cystic swellings, resembling large tubal tumors presented, which proved to be the distended vagina bulging in front and behind the uterus. It was apparently normal. A part of the vaginal wall was eroded and discolored and did not disappear for some time after the excision of the hymen.

Dr. E. E. Bull recalled one example of this condition in a girl, eighteen years of age, who had never menstruated. The tumor reached above the umbilicus but consisted simply of the distended vagina. The uterus was apparently normal and menstruation has occurred regularly since the operation.

Dr. A. Brothers recalled three examples of this condition and thinks it is not so extremely rare. He keeps his patients in bed after such an operation.

Dr. Goffe, in closing, said that his patients had not had any vicarious menstruation. It seemed to him that the great pressure had so changed the endometrium that there was little danger of absorption, provided nothing was put into the vagina. He had only seen these two cases.

Further Results in the Use of the Modified Champetier de Ribes Balloon.—Under this title Dr. James D. Voorhees read the paper of the evening. He first noted the increasing number of difficult and operative labors, especially in large cities, due in part to late marriages, as in older primiparæ the soft parts were more rigid, the joints firmer, the bones of the fetal skull were harder, and the uterine contractions were weaker; due also to the mode of life and surroundings of women in the large cities. For the purpose of starting labor, of strengthening the pains and of assisting the dilatation of the cervix, he considers the use of the conical rubber dilator to be of more value than anything else. As in his first series of cases in the service of the Sloane Maternity Hospital, the dilators employed were the Champetier de Ribes, modified in such a way as to be stronger and thus to withstand the uterine and abdominal contraction, to resist the tension when filled with fluid, and to permit of a certain amount of traction without rupture. For this purpose there is a foundation of thin canvas instead of silk, covered by thicker rubber and firmer seams, especially where the tube joins the ampulla. Anesthesia is only used for their introduction, when a preliminary divulsion is required, or when the cervix is high, or if the patient is nervous and sensitive. Ordinary sponge forceps and a Davidson syringe are the only instruments required. The largest bag possible is used at the outset, and slowly inflated with slight traction so as not to displace the presenting part. His present series of cases are taken from 200 patients in his private practice and from 4,272 deliveries that have occurred at Sloane since the publication of his first series. From these two series of cases he concludes: (1) That the best artificial hydrostatic dilator of the cervix is a modified Champetier de Ribes balloon, because it is most like nature's bag. At Sloane it has been used 260 times to 73 manual dilatations, and in his

private cases as often as one in every five deliveries. (2) In dry labor by hastening the dilatation and by preventing the further escape of liquor amnii, fetal mortality is diminished. (3) In protracted labors, even when there is some obstruction, by shortening the first stage, the patient is less exhausted and better able to withstand operative procedures. (4) For inducing labor, it is the best method, it is successful where the bougie has failed, unless anesthesia is contraindicated in a case in which the cervix is long and undilated. A combination of both the bougie and bag is valuable, as used by Cragin and Norris. It is especially useful in cases of contracted pelvis, and in eclampsia, can be used oftener than is generally thought, thus avoiding the lacerations and mortality not uncommonly the result of accouchement forcé. (5) In placenta previa, especially the marginal variety, it will also avoid the lacerations of the uterus that are so commonly the cause of death and will lessen the fetal mortality.

Dr. Broadhead, in the discussion, stated that he had made extensive use of these balloons for the past five years and had found them to present all of the advantages that Dr. Voorhees had mentioned. He also was in accord with the opinion that they, combined with medical treatment, give better results in cases of eclampsia with an unyielding cervix than does accouchement forcé.

Dr. J. Clifton Edgar recalled how much better the original Champetier de Ribes bags were than either the Barnes' or McLean's modification, but in a short time their objectionable size was modified by one of the assistants in the Tarnier pavilion. Thus modified, he had used these bags satisfactorily for a number of years, although in one case the fetal head was displaced. It has largely taken the place of bougies in his own practice, although he still uses the latter in some cases to stimulate pains, and in some instances supplements the use of the bag with them, as Dr. Cragin does. He had employed them in the marginal variety of placenta previa, but would hesitate to do so in the central type, preferring to pack the cervix and vagina with sterile gauze, thus allowing the cervix to soften sufficiently to do a manual dilatation without danger of rupturing the uterus.

Dr. Franklin A. Dorman said that in teaching graduate students, whose previous practical experience had taught them the difficulties of treating a rigid cervix, eclampsia and placenta previa, he had noted the enthusiasm with which they received the description and method of introducing of these bags. In placenta previa of the central type he considers the use of these bags to be the most conservative method—with the exception, perhaps, of Cæsarean section—but does not agree, however, with the statement of Dr. Voorhees that the largest possible bags should be introduced at once. By using a small bag placenta is exposed more gradually and the danger of hemorrhage is minimized. He had seen the fetal head displaced when too large a bag was used, and in some instances the membranes have ruptured and the cord has prolapsed; and he has also seen the cervix torn when they were unskilfully introduced, but such accidents should nor occur if they are carefully introduced, and should weigh very little against their use.

Dr. Robert A. Murray agreed with the treatment of Dr. Edgar for central placenta previa. He sometimes used the Barnes' bag or a Champetier de Ribes after the cervix has become softened from the use of gauzes. He thought that, even after a severe hemorrhage, immediate delivery is often unnecessary, if the extremities are bandaged, the patient is elevated and saline infusion is used.

Dr. W. S. Stone thought the paper of Dr. Voorhees demonstrates that obstetrics is a scientific branch of medicine, which every one cannot practice equally well. He thought that the introduction of these bags required some skill and for one familiar with their use there would be considerable risk in injuring the cervix, although he did not bring this up as an objection to their use, but only to emphasize the point that special skill is required to practice scientific obstetrics.

Dr. Voorhees, in closing the discussion, said that a displacement of the fetal head had occurred in a few instances, in which a large bag was introduced and dilated too rapidly. Where haste is required and you have not the bags at your command he considers tamponing a suitable measure in dealing temporarily with placenta previa. He has seen a few cases of prolapsed cord in which the introduction of the bags was improperly managed. He agrees with Dr. Murray that one should often depend upon the softness of the cervix rather than the amount of dilatation. In regard to the size of the bag it was a general rule to use the largest bag possible.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

Section on Psychological Medicine.

(Continued from Page 1008.)

"Insane or not Insane" not Biological.—Dr. David Yellowlees (Glasgow) asserted that the legal principle "insane or not insane" was untrue to nature. There was no such definite and absolute division. Humanity stood on a great slope. On the top were the sane, stable, reasonable, self-guiding people; at the bottom were the idiotic, the hopelessly demented, and deluded. On the slope, and at varying heights on it, were many persons defective according to their height on the slope; their mental stability, knowledge, judgment, power of self-guidance and self-control were, in varying degrees, less than in ordinary sane people. Whatever the law might say, those persons on the slope must be dealt with specially. They were not like other men, and when they committed crime they should be judged more leniently and punished less severely (if at all), according to their position on the slope. There had been at least three cases in the Scottish law-courts where this principle had been acted upon, and in which punishment was mitigated on account of the mental deficiency, and sentence of death was not abrogated, but commuted to penal servitude for life. A course of insanity, with clinical teaching, should be made part of the legal training.

Degeneration—What is it?—Dr. Conolly Norman (Dublin) drew attention to the fact that the modern Continental theories of "degeneration," which have never found much favor in England, were singularly different from the doctrines laid down by Morel in his original treatise. He proceeded to comment on the violence which often (happily not to-day) characterized the discussions on this subject. It seemed to him that there was a tendency to obsession both on the part of the physicians and the lawyers—one side oppressed with the fear lest those of unsound mind might be unjustly and cruelly punished, the other lest wicked criminals should escape their merits through the machinations of foolish doctors. He listened with surprise to Sir Herbert Stephen's

letter because, as the speaker understood the statement, his "class three" was so constituted as to include every case in the least degree doubtful, and the great majority of those cases in which any question could arise. The speaker believed in the solidarity of the mental functions, and did not at all consider that the fact that a man understood the nature and qualities of the acts he performed carried with it responsibility. They could not separate the will from the other functions, or refuse to allow of its existence at all, as Hobbes did when he called it merely the latest motion in deliberation. As to the question of responsibility in court, the speaker held that this was not a question for the physician, and pointed out that Griesinger had long ago laid down this maxim, and had acted upon it when called upon for his opinion on this point. With reference to impulse, this plea had, of course, been abused, but he was glad to see that Dr. Mercier had clearly recognized that there was a distinct condition of impulse. Every clinical observer knew that this state had its very distinct and recognizable mental and even physical symptoms, and that the condition could rarely or ever be doubtful.

Others who read papers on allied topics were Dr. E. S. Talbot, of Chicago, J. Beard, of Edinburgh, and W. König, of Berlin, who gave masterly addresses on Heredity.

Dementia Præcox.—This paper was read by Dr. Conolly Norman, of Dublin. He said in recent years the doctrine of "precocious dementia," as deduced from the later works of Professor Kräpelin, of Munich, has acquired a great vogue. Its author, during the long period when he filled the Chair of Psychiatry at Heidelberg, attained the highest eminence as a teacher and as a writer. His work in psychophysics has much enhanced his reputation for exact observation. Even the fact that the successive editions of his text-book contain variations and modifications of former views very unusual in such volumes has only served to increase the confidence felt in his frankness and good faith. His theories as to classification have been very generally accepted in Germany, France, and Italy, and have attracted much attention in America. It is true that in England they have been comparatively little noticed, but that is probably less due to any feeling of their unsoundness than to the very general neglect of the progress of clinical psychiatry which has prevailed of late years in this country. The existence, either as a distinct entity (which Kräpelin does not affirm, though some of his followers do) or as a practically useful homogeneous clinical group, of any condition which can be called by the name "dementia præcox" does not, in his opinion, admit of proof, and is, therefore, here disputed. The collective grouping of hebephrenia, katatonia, and the paranoid forms makes so vast a congeries that it is impossible to perceive any connecting link between the items of the mass, save in their origin at the age of adolescence and in their supposed unfavorable termination. So much is endeavored to be put within one loose definition that the continent bursts and the contents escape from grasp.

The two first forms—katatonia and hebephrenia—seem to him to have considerable value as types of mental disease. Well-marked cases have, as all recognize, very remarkable facies. It does not detract from their value as types that they run into each other. A good case of katatonia seems at first slight to distinct, by its mental and physical symptoms, that we feel almost compelled to believe that here at least we have a specific disease. The studies of Bruce and others point strongly in this direction also; but our arrival at this conclusion is barred by the difficulty which intermediate forms interpose—forms that are many times more frequent than the pure and typical cases. The very term "dementia præcox," applied in common to affections such as katatonia on one hand, and, on the other, those forms of chronic delusional trouble which need much refinement to distinguish them from ordinary paranoia, would seem to indicate that the striking mental and physical features of katatonia are not sufficient to constitute it a separate disease. The same may be said of hebephrenia. While its exquisite forms seem to establish at least a remarkable type, its margins are so indefinite that it eludes satisfactory definition.

Paranoid Forms.—But the chief difficulty in the clinical comprehension of dementia præcox is to be found in the paranoid forms. There is absolutely no criterion whereby one can distinguish these from paranoia unless one suddenly drops the method of inclusion which has been followed, and reverts to the method of exclusion, holding that nothing can be called paranoia except the most exquisite pure and typical cases. This, however, will hardly save us from the followers of Kräpelin, one of whom has not long since, in the *Zeitschrift f. Psychiatrie*, freshly described at great length a case given by Kräpelin in his clinical lectures as an example of paranoia; but the disciple has outrun his master, for in commenting on this case he submits the view that it is really an example of precocious dementia. Even Lugaro exhibits the same tendency and makes a remarkable deduction in recently describing a case of an elderly man who, after an attack of depression with attempted suicide and consequent trauma capitis, became liable to recurrences of delusions of persecution associated with auditory hallucinations. This case Lugaro seems to consider was probably one of precocious dementia. It is difficult to see what value is to be attached to a term so loosely used.

With regard to origin at the adolescent period, the peculiarities of cases which begin at this epoch are largely the physiological characteristics of a particular period of mental growth exaggerated and distorted by disease, and are therefore not to be regarded as indications of a specific affection. Disease attacking an undeveloped organ has a natural tendency to interfere with its further development. This we see in every tissue from dental to cerebral. Hence it may often be that cases commencing at the period between puberty and adolescence, and not recovering, retain the impress peculiar to the adolescent mind when the patient's actual age is far past adolescence, but this does not go to prove that there is anything specific in the affection running this course. Kräpelin admits that any of the symptoms characterizing dementia præcox—verbigeration, playing with words, automatic obedience, stereotypy, catalepsy, grimacing, etc., may occur in individual cases of other forms of insanity besides precocious dementia. Furthermore, though 60 per cent. of cases occur before the twenty-fifth year, yet cases may begin much later; nay, Kräpelin quotes with approval an observation of Schröder's of a case beginning at fifty-six years. Again Kräpelin emphasizes the fact that in 20 per cent. of cases which overtly appear at the usual period, investigation proves eccentricity, etc., from the very earliest age. Finally, "causes" are described for dementia præcox as for other mental

affections, and among these cases are typhoid, scarlet fever, imprisonment, the puerperal state, etc. Surely these are very hard sayings. It is difficult to ask one to believe in the existence of a disease so little differentiated from everything else. But it needs here also to be again pointed out that Kräpelin does not claim so much for his precocious dementia as do his followers. He expressly states that the existence of dementia præcox as a separate and distinct disease is doubtful, and he points to the prognostic advantage of stringing together what may after all later on prove to be separate affections by the common thread of their tendency to dementia. In conclusion, he said, that considerable value attaches to the discussion of Kräpelin's doctrine of precocious dementia, though one may draw conclusions quite the opposite of his. First of all, in opposition to the notions current a quarter of a century ago, it is important to clearly recognize that all cases of mental disturbance are not favorable according to the youthfulness of the person attacked, but that a large number of people in whom insanity appears before the mind has fully developed suffer from the consequences of a permanent arrest of mental growth, do not recover, and exhibit during, perhaps, a life-long illness the peculiarities of the period of life at which their development stopped. That there are any definite indications by which such unfavorable cases can be recognized or foretold, and that they form a definite, even though a multiform, group of mental diseases, must be held to be entirely unproven. Classification is not a very important thing in the existing state of psychiatry, except for convenience in teaching, and the mere nomenclature of disease is of little value save as an index of our knowledge or ignorance. Taking note, however, of natural groups is of vast importance with a view to prognosis and to treatment, and it is therefore safer and more scientific to have no classification than one which confuses together under one denomination groups that have no natural connection, more particularly when such classification tends to establish counsels of despair.

Section on Medicine.

Tuberculous Pleural Effusion and Pneumothorax. Dr. William Osler said that at the threshold of the discussion the question arises, Which are the tuberculous pleurisies? Clinically these great groups of pleurisy with effusion may be recognized: (*a*) pyogenic, (*b*) the meta-pneumonic, and (*c*) the tuberculous. During the past twenty-five years the evidence has been accumulating in favor of the tuberculous nature of a large proportion of all cases of simple sero-fibrinous pleurisy. The exact percentage is hard to determine, but, in the absence of pneumonia or sepsis, the very existence of a pleural exudate is in itself sufficient to raise a supicion of tuberculosis. This view is based upon: First: The finding of tubercles in cases of sudden death in pleurisy with effusion. The literature contains many such instances in which, as a rule, tuberculosis had not been suspected, but the pleurisy had been attributed to cold, to injury, or to rheumatism. The traumatic cases are still more striking, and the evidence has been accumulating to show the tuberculous character of the pleurisy which follows falls or blows in the chest. Secondly: The frequency with which healed tuberculous pleurisy is met with in the post-mortem room. From Létulle's laboratory an interesting study has been recently published by Trouvé: among 303 cases of other diseases, the pleura was involved alone in 59. Thirdly: A study of the exudate: (*a*) The general characters present nothing distinctive. In acute cases it may be of turbid and dark brown color, with much fibrin, and not infrequently blood. In the more chronic cases it is clear, or has a slightly greenish of opalescent tint. The fluid is sterile as a rule, or the bacilli are difficult to find. (*b*) Cytological. The studies of Widal, Gull, and others have shown that in tuberculous cases the exudate contains small mononuclear leucocytes. (*c*) Bacteriological. The tuberculous exudate is stated to be sterile, but with the newer methods the bacilli may be found in a considerable proportion of the cases. After contracting into a fairly small volume the coagulum is removed and placed in a pepsin HCl mixture. When well digested in the thermostat the fluid is centifugalized and the sediment searched for bacilli. Of the last twenty cases in his series bacilli were present in the exudate in 4. (*d*) Inoculation. When the centrifugalized sediment or a large amount of the exudate is used the results have proved positive in a large number of cases—65 per cent. (Eichhorst) to 85 per cent. (Le Damany) in 55 cases quoted by Chevastelon. (*c*) The observations in the agglutination test are, as far as he knows, not extensive enough to warrant conclusions to be drawn from them. Fourthly: The presence of tuberculous foci in other parts—an old bone lesion, an adenitis, a fistula in ano, an epididymitis, or a chronic peritonitis. A latent pulmonary focus is not infrequent. Of 195 cases of pleurisy with effusion admitted to his wards, exclusive of all patients with obvious pulmonary tuberculosis, there were 30 in which tubercle bacilli were demonstrated in the scanty sputa. Repeated examinations were made in each case, and even when the patient insisted that he had no cough, he was urged to try to spit out anything he could. In one case fully a score of examinations were made before bacilli were found. Fifthly: Many cases of pleurisy with effusion subsequently became phthisical, the percentage varies from 15 per cent. (Cabot) to 45 per cent. (Hodge). Of 86 cases from his wards in which the after-histories were studied by Dr. Hamman, 34.8 per cent. became tuberculous and died. Grouping together the statistics which have been gathered on this point, the percentage is about 30. Sixthly: A characteristic tuberculin reaction has been obtained. Beck gave tuberculin to 68 patients with pleurisy, and 50 reacted (73.2 per cent.); F. W. White gave tuberculin to 8 cases of acute pleurisy, and 7 reacted. And, lastly, certain clinical features, as insidious onset, protracted course, early thickening with retraction, hemorrhagic character of the exudate, etc.

It is not always possible, nor is it necessary, to obtain this positive evidence. It makes no difference in the local treatment, and for general purposes it is best to assume every case to be tuberculous, unless there is very good reason to think otherwise. The acute sero-fibrinous and the subacute and chronic serous forms are the most important in connection with this discussion. It is interesting to note how often the acute form is a terminal event in chronic diseases, but a considerable proportion of the cases in young, healthy persons belong to this group, in which the suddenness of the onset and the intensity of the symptoms may be marked. The exudate is sero-fibrinous, and there is much fibrinous plastering on the surfaces. The fluid has a brownish tint, and is not infrequently bloody. In the subacute and

chronic serous form the exudate is more often opalescent, with scanty cell elements, and there are no fibrin flakes on the pleural surfaces, which are smooth and not acutely inflamed. The purulent tuberculous pleurisies are usually chronic, but there is an acute suppurative form running a course of great intensity, with abundant bacilli in the pus. To be profitable a discussion should be limited to questions still in dispute, or to points which new knowledge has brought into prominence. He proposed for discussion, first, the value of early and repeated aspirations in the acute forms; secondly, the uselessness of drug treatment; and, thirdly, the need of more careful after-treatment, local and general.

Aspiration has been in use for more than half a century, but it has been as an adjunct or supplementary to other measures, not as the treatment itself. Most of us have followed H. I. Bowditch's original indications (1850)—to tap when the symptoms were urgent, or the side was full, or in a moderate effusion, if it had lasted more than a few weeks, and was disposed to resist ordinary modes of treatment. Of late years there has been a tendency to resort to tapping much earlier, and not to wait until the fever has subsided—to make tapping an *indicatio morbi*, not simply an *indicatio vitalis*, or symptomatic, as, following Bowditch and Trousseau, we have hitherto done. The advantage of this plan was emphasized by Castiaux as early as 1873. The question was forcibly brought before the profession about eighteen months ago, when Dr. Delafield reported 200 cases of pleurisy, with effusion, treated at the Roosevelt Hospital, New York, from 1886 to 1901. In the first 82 cases medical treatment and aspiration were employed, in 118 aspiration alone. One hundred and eighty-two patients left the hospital cured, six left the hospital within ten days after aspiration and probably recovered; six were improved, but the results were uncertain, and in six there was no improvement. Sixty-four patients were cured within a week of the aspiration. There were no deaths. Dr. Delafield remarks that in private practice the results are still better: "In the fortunate cases, within twenty-four hours there is no more fluid and no more pleurisy. In a large number of cases the pleurisy is cured within a week." Those who know the highly-trained clinical judgment of Dr. Delafield will be able to appreciate at its true value this important contribution. He had been in the habit of treating pleurisy with effusion either by what is called the "thirst" method or by tapping and the administration of tonics and occasionally of the iodides and the use of counterirritation. In the eighteen months since the appearance of Dr. Delafield's paper there had been 22 cases in the wards, two of which were admitted as the effusion was subsiding, and were not tapped. In the others the effusion was treated by aspiration alone. In five the condition was chronic on admission, the effusion having lasted for two or more months. Four of these left the hospital improved and one well. The other 15 were discharged well. Only three of these cases were admitted in the first week, and the earliest tapping was done on the tenth day. Five cases were tapped twice, two three times, and one four times. Of this group of 20 cases, seven were shown to be tuberculous; in four bacilli were demonstrated in the exudate, in two bacilli were found in the sputa, both acute cases, which had not been under treatment for any pulmonary disease. One patient, ill for two and a half months on admission, was discharged improved, and was readmitted with miliary tuberculosis ten weeks later. These results are very brilliant, and not to be compared with Delafield's. The average stay in hospital was thirty-two days, the shortest was six days.

The Treatment of Chronic Renal Disease.—Dr. Hale White said that the title of this discussion is the treatment of chronic renal disease, but the conditions of kidney known as chronic nephritis, chronic Bright's disease, the granular kidney are so much more frequent than other chronic diseases of the kidney, that he confined himself to them. The difficulties of the subject are very great; for, although all are familiar with the morbid histology of chronic Bright's disease, its pathology is unknown and why it is fatal is a question; also, the health of sufferers from it fluctuates so, apart from treatment, that it may be difficult to say whether any particular treatment is beneficial. Therefore, it is probably best to discuss it under two heads—namely, the treatment of particular symptoms, and that employed owing to theoretical views as to the nature of the disease. A symptom which has been energetically treated is albuminuria, in his opinion quite wrongly, and often with disastrous results. The mere presence of albumen in the urine is usually of itself of little importance except as a help to diagnosis. It is so often met with in specific fevers, heart disease, renal calculus, cystitis, and other disorders, that about half the invalids who have albuminuria do not suffer from Bright's and yet those who try to treat it when it is associated disease, with Bright's disease neglect it in other maladies, and forget its ferquent occurrence in healthy youths. All doctors of long experience can call to mind persons who have passed albumen in their urine for twenty years or more without harm. A little calculation will show that a few grams only are passed daily in most cases of chronic Bright's disease, and the loss of proteid in this way is quite trifling, and could easily be compensated by a little more in the food. Whoever heard of death due to albuminuria? He had great sympathy, he said, with a celebrated physician who, when the treatment of albuminuria was much in vogue, said if he ever had it he trusted he would never know it. Much harm may be done to patients with chronic Bright's disease by frequent examination of the urine, for they become depresed unnecessarily if the quantity of albumen increases a little, and unduly elated if it decreases. Often, too, the examinations are valueless for comparison, as only a rough percentage of albumen is stated, without any reference to the total amount of urine passed in twenty-four hours. Albuminuria is a very important help to the diagnosis of all forms of Bright's disease, and steady fluctuations in its quantity are of great aid in enabling one to estimate the progress of acute and subacute cases; otherwise it is unimportant, and is, indeed, often slight for some time before death from chronic Bright's disease. But not only is the mere symptomatic treatment of the albuminuria wrong, but, as he had pointed out in a paper written eleven years ago, a milk diet, which is chiefly relied upon to reduce albuminuria, frequently fails to do so, and the sufferer from chronic Bright's disease is in many ways worse for the milk.

He then spoke of the symptoms connected with the cardiovascular system. Two extremes are met with—both bad—in chronic Bright's disease. Some patients have such a hypertrophied heart and high-tension pulse that they die of cerebral hemorrhage; others have a feeble pulse of low tension, a dilated

heart, possibly mitral regurgitation, and they die from cardiac failure. Those of the first group must keep down their arterial tension; physical exercise must be gentle, excitement must be avoided, the bowels must be loosely open once every day, partly because so doing helps to keep the pressure low and partly to avoid straining at stool, for that, like any sudden exertion, raise the blood pressure. Cerebral hemorrhage has often occurred in the water-closet. Meals must be small; alcohol and much meat or preparations of it, as soup, beef-tea, and meat essences, must not be taken, as both alcohol and the extractives of meat raise blood pressure. Little fluid should be drunk; digitalis and other drugs which raise blood pressure are especially harmful, but an occasional venesection is beneficial. Those in whom the pressure is low and the heart weak often owe their condition to treatment. They have been kept too exclusively on milk or farinaceous diet. Over and over again it is forgotten when treating disease that you cannot starve one part of the body without starving the whole. Under the impression that a small supply of milk is the best diet for diminishing the work of the kidneys, the patient with chronic nephritis is starved and his heart suffers starvation—a state of affairs made worse by the fact that as the arteries thicken the heart's work increases. In the paper to which he had alluded, cases are given which show how such patients improve when they are allowed an ordinary diet containing a moderate amount of meat, often, too, a little alcohol helps them. Not only does their circulation benefit, but as they are no longer starved they feel better in every way. Some patients with chronic Bright's disease are kept too much in bed; the heart, like the rest of the body, becomes flabby, improvement in all directions follows getting up and about, the circulation and digestion are strengthened, and the patient feels better. Much judgment is required to estimate the amount of exercise a patient may take. Some, by their doctor's orders, take too little and become fat; this is particularly bad in chronic Bright's disease, for the heart often has as it is too much work owing to the arterial thickening, and therefore only harm can follow if it has to pump the blood through an additional amount of fatty tissue. Whether, when symptoms of uremia supervene, much fluid should be drunk will be discussed later, but for the greater part of the life of a sufferer from chronic Bright's disease he will be best if he only drinks a normal quantity for that will be the best for the circulation, although probably the evil effect of the heart of a large amount of fluid in the vessels has been exaggerated. Many diabetics drink largely, and yet the heart in diabetes is small. The error of so lowering the blood tension by diminishing the intake of fluid so as to give the heart too little work is hardly ever likely to occur. To sum up, the whole object as regards the circulation is to keep the vascular tension normal without the aid of drugs.

Excepting edema, caused by cardiac failure—and then it is best treated by trying to strengthen the heart—it is not sufficiently common in chronic intestinal nephritis for it to often require treatment, but it does in the chronic tubal variety. Slight or moderate degrees are best treated by posture; the legs may be raised if the edema is of the feet, or the patient may be turned first on one side and then on the other if it is of the back or lungs. Much may be done by limiting the amount of fluid drunk and also by seeing that the bowels are regularly well open and that the motions are rather watery. One can often do very well without diuretics, but if the state of the kidneys is very chronic and the blood tension is low some caffeine or a pill containing a grain of each of mercury, powdered digitalis, and powdered squill may be of use, but it is a mistake to depend much upon diuretics to relieve renal dropsy. Diaphoretics are of help; they will be discussed when speaking of uremia. The most efficient way to get rid of edema is either with needles or Southery's tubes to puncture the legs, which are then kept dependent; but there is no operation in which aseptic precautions are more necessary, for edematous tissues are an easy prey to streptococci, and fatal inflammation easily supervenes

To Avert Uremia.—It seems reasonable also to try to avert uremia by the same plan, therefore if a patient suffers from chronic Bright's disease the bowels should be well open daily; the sweat glands should be kept mildly active, but frequent excessive sweating is very undesirable, for it cannot be induced without damaging the circulation, and, as has been already pointed out, this must be maintained as healthy as possible. But the patient may have a warm bath every night, rub the skin quickly after it, and then instantly get into a warm bed. Woolen garments should be worn next to the skin. Egypt is the ideal climate, for the temperature is high and the humidity very low, hence the perspiration rapidly evaporates, and the patient is not oppressed by his sweating. But as the humidity is so low the air feels very cold at night, especially if there is a wind, consequently the patient will often require to clothe very warmly after sunset, and this is especially true if he is on a boat on the Nile. Further, far up the Nile, as at Assouan, it may be difficult to get food proper for an invalid. For a few patients an occasional Turkish bath may be allowed, but usually not, on account of the harm that may be done to the circulation. Keeping the sweat glands active not only aids elimination but helps to prevent or remove edema. Perhaps this is the best place to draw attention to the fact, often forgotten, that a close relationship exists between the skin and the kidneys. The harm of chilling the skin may happen in more ways than one: excretion by sweat is stopped, contraction of the cutaneous vessels tends to raise the blood pressure and throw more blood into the kindeys; it also tends to raise heat production, and possibly therefore to increase some poisonous products of metabolism. To avoid chilling of the skin clothing should be warm, and it is especially necessary to change any that has become wet either from rain or sweat.

There is not much to say about the treatment of individual symptoms of uremia beyond what has been said about that of uremia generally. One should not be too hasty in attempts to check diarrhea and vomiting, for it should be remembered that they are eliminative. The severe headache so often associated with a high-tension pulse is sometimes relieved by nitrites, and both it and the sleeplessness may be diminished by a hot bath immediately before going to bed. If a hypnotic is required chloralamide is one of the best. Uremic dyspnea is often very hard to deal with. In addition to the general treatment of uremia nitrite of amyl may give relief, and sometimes oxygen is of use.

(To be Continued.)

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 85. NEW YORK, SATURDAY, DECEMBER 24, 1904. No. 26.

ORIGINAL ARTICLES.

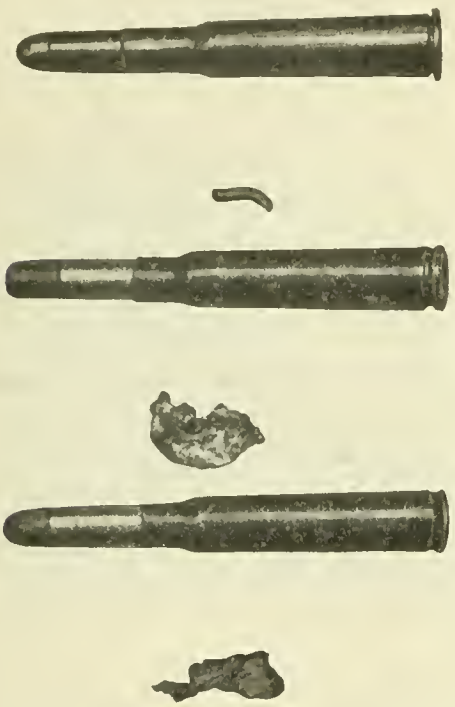
THE ALLEGED USE OF DUM-DUM BULLETS IN THE JAPANESE-RUSSIAN WAR.

BY GEORGE RYERSON FOWLER, M.D.,

OF BROOKLYN, NEW YORK.

THE accompanying reproductions of photographs were received by the writer from Dr. Wm. B. Noyes, to whom they were sent by Mr. Franklin Clarkin, Special War Correspondent of the *New York Evening Post*. The photographs were taken immediately after the battle of Liao-Yang, and represent some of the unusual effects of modern rifle projectiles, together with cartridges, said to have been found upon Russian prisoners, and fragments of the jackets of bullets. The fragments of jackets or coverings of bullets were recovered from wounds in Japanese soldiers.

Fig. 1.



Reproductions of photographs of cartridges said to have been found on Russian prisoners captured at the battle of Liao-Yang, and of fragments of mantles or jackets of bullets. These fragments were removed from the wounds of Japanese soldiers.

The cartridges show a portion of the jacket cut away, and have undoubtedly been tampered with. The fragments of jackets taken from the wounds are such as might have been imprisoned in the tissues after having been separated from bullets deformed either previously or subsequently to their entrance into the body.

The phase of the subject of interest to the surgeon relates to the manner of production of these wounds, and the possibility of their being caused (1) by bullets belonging to the regulation arm, but from which the covering or jacket had been partially removed with the intention of producing a mushrooming effect upon striking the body, and with the result of inflicting extensive shattering and mangling of the parts; (2) by the shattering effects of the modern oval projectile under exceptional conditions, even when the jacket remains intact; and (3) by modifications of the normal course of the bullet in its flight (ricochet shots), attended or otherwise by disturbances of the jacket.

Fig. 2.

Bullet Wound.—The note accompanying this photograph states that the soldier was shot at the range of about 500 meters while kneeling, and that the bone was broken and the arm extremely swollen.

The distance at which the soldier was brings the case within the distance where the most destructive effects may be expected, even from a projectile, the metal jacket of which had not been tampered with. These destructive effects include extensive shattering of bone and the tearing of the soft parts along the canal and at the point of exit.

1. That these wounds could well have been produced by bullets, the jackets of which had been removed in whole or in part, is at once evident. The mushrooming effect at the place of exit is well-shown in several of the photographs. In fact, this effect is shown to such an exaggerated extent in some of the photographs that it seems incredible that so much

damage could be inflicted by so small a projectile, even when spread out into a mushroom shape, as claimed. The comparatively small wound of entrance, however, as shown in Fig. 2, sets at rest any doubt upon this point in this particular case at least (see comment). The alleged wound of entrance shown in Fig. 3, however, certainly appears more like a wound of exit, and this is

Fig. 3.

Bullet Wound.—The accompanying note states that the soldier was shot at a range of about 300 meters while lying, and that the bullet struck on the left forearm and made its exit near the elbow and grazed the upper arm. The entrance is oval, 4 cm. long and 3.5 cm. wide. The exit is circular and the diameter is 2 cm.

The appearance presented in this case, and the fact that the soldier was lying down when shot, makes it more than probable that he was struck by a ricochet shot, the bullet traveling near the ground and encountering some object in its course, and that only a portion of the bullet escaped and made the furrow in the arm. Either this or the shot took the opposite direction, making first the furrow in the arm, then the comparatively small wound in the upper part of the forearm, and finally making its exit at the larger wound in the forearm.

strengthened by the comparatively small size of both the furrow in the arm and the upper one of the two bullet wounds in the forearm. In Fig. 4 both the wounds of entrance and exit are shown; the comparative size of the former suggests that either the bullet was deformed before entering the body, or that it has been converted into a ricochet shot (see comment). In Fig. 5 the wound of entrance is shown, but no wound of exit, which leaves room at least for the supposition that none existed, the bullet having lodged in the body, a not uncommon occurrence in ricochet shots (see comment). In Fig. 6 the fact that the wound of entrance was circular is mentioned; other than this no information concerning it is given (see comment). In the note attached to Fig. 7 an enormous wound of exit is shown, suggestive of a shrapnel bullet wound, such as is shown in Fig. 8.

It would appear, therefore, that no proof exists that these wounds were made by bullets such as shown in the photographs, even though these were found with a portion of the jacket removed; the bullet belonging to the regulation arm, with its jacket similarly tampered with, will produce the same effects.

2. As to the shattering effects of the modern oval projectile, even when the jacket remains intact, the first point to engage our attention in this connection is the explosive effects of the so-called "projectile air" in wounds. It has been been claimed that, when a firearm with high-muzzle velocity strikes an object while it still possesses what is known as great internal energy, it compresses and drives ahead of it into the tissue a small column of air. This column of

Fig. 4.

Bullet Wound. The soldier was shot at the range of about 200 meters, while kneeling. The entrance and exit are both very large. The wound resembles one made by the fragment of a shell. The soldier affirms, however, that no shells were coming that way at the moment.

This injury might well have been caused by a bullet which had become deformed before entering the body by striking some object (ricochet shot), or, passing through some other body which, without necessarily disturbing its mantle, converted it into a "Querschläger."

air exercises an expansive force, and is said to produce the explosive effects sometimes noted along the bullet channel and at the point of exit. The explosive effects are said to be proportional to the size of the bullet, its obtuseness at the front, and its velocity, since these necessarily govern the amount of explosive air driven before it.

In the days of large and blunt rifle projectiles

the theory of "projectile air" was a tenable one, the more so for the reason that experiments, consisting of the dropping of bullets from a height into water, showed that a certain amount of air was forced into the water with it, as well as a further demonstrable portion of air enclosed by the water in the opening made by the bullet in entering and passing through the

Fig. 5.

Bullet Wound.—The note states that the wound of entrance, as shown in the picture, is 3 cm. long and 2 cm. wide.

The oval appearance presented by this injury is such as is produced by a bullet which loses its position relative to its long axis, and strikes the body sidewise or crosswise (Querschläger effect). If there is no wound of exit this would strengthen this view, since, in ricochet shots the "internal energy" is lost and the rotation imparted to it by the rifling of the barrel is disturbed.

water, seemed to sustain the theory. The air carried in by the bullet was estimated at twenty times the volume of the bullet itself (Longmore), It is to be doubted, however, whether a modern small-bore bullet could produce sufficient forced air pressure as to cause the destructive effects shown in these photographs.

Hydrodynamic pressure, it is claimed, influences the action of the bullet in a marked degree, and is used at the present time to explain the explosive or shattering effects of the entrance of the projectile into the tissues. The pressure effect rests upon the incompressibility of water and the narrowing of the space which it occupies in the tissues as a result of the transfer of pressure in all directions. It therefore follows that the most marked destruction takes place in organs containing the most water. The effect is the more intense the more fluid the organ contains, and the shorter the distance at which the shot is fired. The effect increases (*a*) with the amount of fluid; (*b*) with the velocity of the projectile; (*c*) with the increase in caliber of the projectile, and (*d*) with deformity of the projectile (Lardy, Encyclopädie der gesammten Chirurgie, Leipzig, 1901).

Kikuzi (quoted by Lardy) showed that an 8 mm. steel mantle projectile showed at 100 meters a hydrodynamic pressure equal to 6.4 atmospheres, while an 11 mm. projectile showed a pressure of 8 atmospheres.

The hydrodynamic pressure theory rests upon a more substantial basis than the hydraulic pressure theory of Busch, Kocher and Reger, according to the results obtained of experiments conducted by the medical department of the Prussian army. These experiments showed that the same explosive effects could be obtained whether the fluid was confined in closed or open

Fig. 6.

Bullet Wound.—The note states that the soldier was shot at the range of about 700 meters, while kneeling. The picture shows the wound of exit, the diameter of which is stated to be 8 cm. The statement is also made that the bone was "smashed." The entrance, located at the back of the arm, is said to be circular. The position of the soldier when struck afforded good opportunity for a ricochet shot and a previously deformed bullet. The "smashing" of the bone and the large area of destruction, go hand in hand. The statement that the wound of entrance was circular does not suffice to fix the fact that mushrooming took place after entrance, in the absence of a statement as to the size of the wound.

containers. In organs in which water is present it was found that the effect depended more upon the amount of fluid which they contained and on the energy of the penetrating projectile than upon the application of hydraulic pressure.

The hydrodynamic pressure theory of the shattering effects of projectiles is generally acknowledged to be applicable to gunshot

wounds of organs containing considerable fluid, notably the brain. The heart, stomach and intestines, particularly when these are struck at short range, may be similarly acted upon. The hydrodynamic theory, however, will scarcely serve to explain the conditions present in the localities shown in the photographs.

The rotation theory has been advanced to explain the appearances of an explosive effect upon the tissues traversed by a bullet from a rifled forearm (Busch). While it is probably true that a revolving body may draw the surrounding parts into the circling influences of its own motion, it is not at all probable that a projectile in striking a body at a high velocity can exercise

Fig. 7.

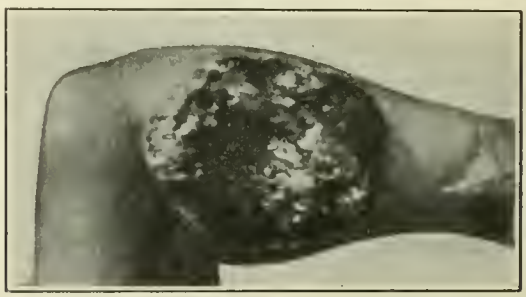
Bullet Wound.—This injury was received at the range of about 600 meters, the soldier lying down. The picture shows the wound of exit, which is stated to be 9.5 cm. long and 5 cm. wide.

The wound of exit only is described in the note. In the position assumed by the soldier when hit, ricochet shots are most likely to occur, the adversary also lying down and the shots traveling near the earth and encountering various objects in their course. It is not stated whether or not the bone was shattered. The injury is not unlike that shown in the next figure, said to be a shrapnel bullet wound.

any such influence. The ratio of the rotation to the velocity renders this impossible, as shown by Lardy. This observer showed by experiments that, traveling at the rate of 620 m. per second, a projectile makes 2,480 rotations upon its long axis, or four rotations per meter. There is no portion of the body where the bullet would be likely to traverse a sufficient distance to render the effects of the rotation other than insignificant. But a single rotation would be performed by the bullet in passing through 25 cm. of tissue. This estimate does not take into account the fact that the rotation is lessened by the resistance which the bullet meets with in its passage through the tissues. The rotation theory, therefore, can be dismissed in so far as it has any bearing upon the question at issue.

3. In considering the third proposition, namely, the effects due to modifications of the normal course of the bullet in its flight, attended or otherwise by disturbance of the jacket, a brief study of the experiments of Peter Bruns (Beiträge zur klinischen Chirurgie, Vol. 19, 1897) may be of interest. This observer experimented with the German model of the self-loading Mauser pistol of 7.5 mm. caliber, at distances of 10 and 20 m. He found that the size of the wound of entrance and exit diminished with the decrease in velocity or increase of the distance. Modifications of the size and shape of the wound of entrance were found to be due to the manner in which the missile struck the surface. When at or near a right angle to the surface, the wound was circular; otherwise it was oval.

Fig. 8.



Shrapnel-bullet Wound.—The picture shows the exit, 15 cm. long and 10 cm. wide. The wound resembles one by explosion. The bone was shattered. The note states that the injury is different from ordinary wounds by the shrapnel bullets.

Glancing shots were characterized by furrows and more or less torn and irregular edges. The point of exit was larger, as a rule, than the point of entrance. The former was liable to greater variations than the latter, these depending upon the elasticity and mobility of the part and the direction which the bullet takes in escaping from the body. Thus, when the projectile leaves the part in other than a direction coincident with its long diameter, the wound of exit is oval or irregular. The largest diameter reported, in which the bullet traversed muscular tissues alone, was less than double the diameter of the projectile (14 mm.). The track of the bullet in the muscles always showed a smooth lumen; the diameter of the latter was generally smaller than that of the projectile.

The influences exerted by shattering of bone upon the damage inflicted at the place of exit is well brought out by Bruns' observations. With more or less comminution of the bones of the extremities, correspondingly large and ragged points of exit of the bullet were observed. To this rule, however, there were exceptions, particularly in the case of the upper arm.

In summing up the observations of Bruns, based upon the experiments above alluded to, it may be said that the damage inflicted by the emergence of the projectile, other things being equal, varies according to the distance. In shots up to 50 m. with the arm employed there is in the majority of cases an area of destruction of muscles which is caused by fragments of bone forced along by the projectile. The area is small, not greater in size, usually than that of a walnut, and the track of the bullet is smooth and either of the same size as the caliber of the projectile or slightly larger; it contains more or less bone debris. In shots delivered from a distance of from 100 to 300 m. there is never any area of destruction of muscles, and the canal of exit is smooth and contains a small amount of bone debris. According to Bruns, the fundamental distinguishing features for near and distant shots lie in the variations observed in the wounds of entrance and exit.

In applying these observations to the conditions under review, it must be admitted that, while the experiments were made by a smaller arm than that employed by the Russian army, still with the exception as to size, the character of the weapon and the projectile were practically the same. In fact, Bruns adds to his observations estimates of the destructive effects at the point of exit of the projectile in the case of the 88 model (Mauser), the limit of shattering effects which he states to be 1,600 and 2,000 m. At the former distance there is still some slight destruction, but this disappears entirely at 2,000 m.

Applying these estimates to the cases in question, even at distances of 200 to 700 m., as stated in the accompanying notes, such destructive effects might be expected, however liberally one might be inclined to interpret Bruns' experiments.

As to the frequency of alterations of the shape of intact mantle bullets, the experiments of von Coler and Schjerning,[1] reported at the Twelfth International Medical Congress, are of value. According to these observers in 4.5 per cent. of all hits deformity of the bullet occurred to a greater or lesser extent. If only hits of the bone are taken into consideration, the percentage is very much increased. In wounds of the soft parts alone there was never noted any deformity of the projectile. Impact against the long bones of the body caused the most marked variations in the shape of the bullet, and in the bones themselves there are certain parts, harder than the rest, which cause the most pronounced deformities. As instances of the latter may be mentioned the linea aspera femoris and the edges of the tibia.

Von Coler and Schjerning call attention to the fact that a distinction must be made between deformity of the projectile caused by the body and those which result from impact upon some object outside of the body. In case the projectile is broken by such impact the fragments may become accidental hits and considerable damage caused thereby, even though the fragments themselves have lost none of their force.

The character and extent of injuries made by deformed bullets were found to be proportional to the deformity of the latter. It was also noted that in all cases of marked shattering effects the result of tearing of the mantle and mushrooming of the leaden body of the projectile there was also extensive destruction of bone, as well as of the soft parts at the wound of exit. These effects were in no way less than those wounds made by the leaden unjacketed mushroomed bullets of former times.

Concerning the question of "ricochet shots" or bullets that have assumed a position more or less sidewise or crosswise before entering the body ("Querschläger") it was found that, in addition to the well-known fact that these deviations from the normal course of the projectile were due to the latter striking such objects as tree-branches, etc., it was found that its passage through several different media, or through bodies that offer more or less resistance to the course of the bullet, produce the same effect. Penetration of several portions of the body without change in position of the long axis of the projectile is declared to be an exceedingly rare circumstance (see Fig. 3 and comment).

The amount of damage inflicted by a ricochet shot depends upon the amount of energy remaining after the bullet has ricochetted. A portion of this energy is expended in overcoming the resistance offered by the air; if, in addition to this, it becomes a ricochet shot and subsequently strikes the body as a "Querschläger," the damage inflicted will be in proportion to the force which it possessed before striking. In any case, however, the damage inflicted will be greater than if the bullet had struck in its long diameter.

The conditions change, however, when the bullet retains its normal force and loses the direction of its long axis only after entering the body. Here the projectile causes extremely destructive effects, tearing along with it, as it were, bone, muscle and portions of the skin.

When it is considered in how many different ways the wounds as shown in these photographs might have been caused in the course of a desperately contested action at short range, in which both high-muzzle-velocity projectiles and shrapnel bullets were used, the difficulties of deciding as to the exact mechanism of their production will be readily appreciated. What with the opportunities afforded for ricochet shots by the projectiles traveling close to the ground as occurs when volleys are delivered and received with the men lying down, the close range at

1 Ueber die Wirkung und die Kriegschirurgische Bedeutung der neuen Handfeuerwaffen. Berlin, 1894.

which the shots were received, and consequently the greater probability of the ocurrence of the shattering effects of modern rifle projectiles undistorted when the hit takes place, and, finally, the acknowledged fact that shrapnel was used in the same action (see Fig. 8)—all go to render it almost impossible to decide the question as to an infraction of the laws of nations upon the evidence afforded.

Concerning the claim put forward that these wounds were made by dum-dum or soft-tipped bullets, Mr. Clarkin writes as follows: "The picture of the cartridges and distorted bullets secured from wounds in Japanese soldiers seems definite enough, but as yet no rifle has been found on the field of battle, or taken from captured Russian prisoners that fits these cartridges, though we have in the preserve, where the war correspondents are kept, certain hunting rifles that seem to fit the cartridges. Wounds caused by these rifles in animals shot in the woods near-by agree with these pictures, at least in regard to the shattering effects on the tissues."

It is incomprehensible that Russian soldiers should, upon the long and weary marches which immediately preceded the battle of Liao-Yang, have burdened themselves with cartridges that did not fit the regulation arm which they carried. As for the distorted fragments shown in the photographs, which, it is claimed, caused the wounds exhibited, it would be impossible to state, in their present condition, even if the pieces themselves were before us, much less from a photograph, whether or not they ever fitted the cartridge shells in question.

In view of all the circumstances, therefore, it would seem as if the evidence presented in the photographs would scarcely justify the accusation that the Russians, in spite of the sentiment throughout the civilized world against the use of dum-dum bullets, and the declaration that their use was contrary to international rights and humanity by the Hague conference of 1899, had resorted to these forbidden projectiles.

RENAL HEMATURIA OF UNEXPLAINED ORIGIN. REPORT OF A CASE WITH CESSATION AFTER NEPHROTOMY.[1]

BY BENJAMIN R. SCHENCK, A.B., M.D.,
OF DETROIT, MICH.;
LATE RESIDENT GYNECOLOGIST OF THE JOHNS HOPKINS HOSPITAL AND INSTRUCTOR OF GYNECOLOGY IN THE JOHNS HOPKINS UNIVERSITY.

Hematuria, as a symptom of renal disease, may be caused by several different affections of the kidney. It most frequently shows itself in cases of calculus and new growth, is not infrequent in tuberculosis, occurs in chronic as well as in acute nephritis, and is sometimes seen in movable kidney. Besides these well recognized cases, there occur others, forming a group, not well defined, but little understood and usually designated by the meaningless terms "idiopathic" and "essential."

During the past one hundred years the views concerning the etiology of the cases in this group have undergone radical changes. Roughly speaking, there have been three periods in the development of our knowledge of such cases, or perhaps one might better say that there have been three epochs, in the course of which the views have been changed, without, however, throwing much light on the underlying cause.

During the first period, the older writers simply classified those cases in which the etiology was obscure as "idiopathic hematuria," referring the cause to such ill-defined and unreliable factors as "exposure to dampness," "catching cold," etc. Thus, Rayer,[1] one of the most brilliant writers of the early part of the last century, in his *Traité des maladies des reins* (1837), a work on kidney diseases in some respects unsurpassed to-day, devotes a whole chapter to the subject, considering idiopathic hematuria not as proven but nevertheless as of common occurrence.

In the following epoch, marked by great activity in the field of histologic pathology, when the attempt was eagerly made to explain all symptoms by reference to pathologic changes, the so-called essential hematuria was lost sight of and it was quite generally held that bleeding from the kidney is always caused by some morbid process.

During the past twenty years, however, these ideas have been again modified, for with the development of renal surgery, permitting the far more frequent examination of the organ presumably diseased, fairly numerous cases were found in which an exploratory nephrotomy, undertaken on account of hematuria, supposedly caused by calculus or tuberculosis, proved disappointing. Nearly every surgeon has had cases presenting bleeding and perhaps pain, has exposed the kidney thought to be at fault and either by needling or by incision, has found nothing whatever to account for the hemorrhage. The kidney has been replaced and in a certain percentage of cases the bleeding has ceased. Such experiences have led to the more or less general belief in the older idea, that renal hematuria can occur, independent of pathological change, and hence our more recent classifications again include a group, variously styled "renal hemophilia," "angioneurotic hematuria," "nephralge hematurique," "renal epistaxis" and "hematuria arising from sound kidneys."

Two different theories have been given prominence in the discussion which has taken place on this subject. The prevailing one is that of Klemperer,[2] who explains the bleeding by supposing that there exists a disturbance of the vasomotors—a paralysis of the vasoconstrictors, causing a dilatation of the blood vessels and a consequent diapedesis of red blood corpuscles—hence the term angioneurotic. Klemperer argues "we have no doubt of the occurence of angio-

1 Read at the annual meeting of the Michigan State Medical Society, at Grand Rapids, May 25 to 27, 1904.

neurotic edema and why should not angioneurotic disturbances take place in the kidney as well as in the skin?"

Senator,[3] on the other hand, presupposes a local hemophilia or a hemophilia confined to one organ. I can find little in the arguments brought forward in support of this idea.

If we admit the possibility of such a cause or causes, the following case observed by the writer in Baltimore, would seem to fall in this group.

Case.—Mrs. J. C., a woman of forty-six years, first consulted me on September 23, 1902. She complained of passing large quantities of blood in the urine and of a persistent backache. The history was briefly as follows: Although never very strong or robust she had had but few illnesses, recalling only an attack of typhoid fever twenty-seven years previously. She had been living in a district where malarial fever prevails but the possibility of her ever having become infected was very carefully excluded. She was the mother of four children and had passed through her marital and menstrual life without mishap.

In May, 1902, five months before the consultation and when in her usual health, she first noticed blood in the urine and began to have a dull backache. At first the hemorrhage was intermittent, but during the summer blood constantly appeared, without much variation in amount. There was no history of sharp attacks of pain and nothing in the patient's account of her illness to point to the source of the hemorrhage, except the fact that the aching had perhaps been a little more severe on the left side. There was no disturbance of micturition and no sediment had been noticed in the urine. Since the onset of the trouble, loss of strength had been marked and there had been a decrease in weight of about six pounds. On physical examination, Mrs. C. was found to be poorly nourished but the color of the mucous membranes was fairly good. The heart and lungs were normal and the pulse, which was 72 to the minute, was of good volume and tension. The abdomen was flat and natural in appearance, with no bulging in the flanks. On palpation there was no resistance and no tenderness. Neither kidney could be felt nor could sensitiveness be elicited in either kidney region or along the course of the ureters.

The blood examination showed 7,000 leucocytes and 65 per cent. of hemoglobin.

Cystoscopic Examination.—With the patient in the dorsal position, a sterile catheter was introduced into the bladder and about 50 c.c. of bloody urine withdrawn. Cultures were made on agar-agar, which subsequently proved to be sterile. The knee-chest position was then assumed and a No. 10 Kelly cystoscope introduced. The bladder walls appeared slightly blood-stained but otherwise normal and the ureteral orifices seemed natural. Renal catheters were then inserted and about 15 c.c. of urine collected from each side, that from the left being intimately mixed with blood, while that from the right was clear. Cultures from both sides proved to be sterile.

Urinary Examination. Mixed Specimen.—Brownish red; specific gravity, 1.022; faintly acid; no sugar; considerable albumin. Abundant granular sediment, consisting of red blood cells and a few epithelial cells; no blood; no casts. *From right kidney.*—Pale yellow; clear; acid; no albumin. Urea 15 grams to the liter. Flocculent precipitate, consisting of phosphates and a few epithelial cells; no blood; no casts. *From left kidney.*—Brownish red; cloudy; neutral; considerable albumin. Urea 15 grams to the liter. Heavy granular precipitate, consisting of blood cells and epithelial cells; no casts. Numerous slides were prepared and stained for the tubercle bacillus, but none were found.

On October 1, three mmg. of tuberculin were injected. There was no reaction. For the next four weeks the patient was kept under observation. During this time, blood was continuously passed and the backache persisted. Specimens from the urine were repeatedly stained and examined for tubercle bacilli but none were ever found. On October 30, the patient was admitted to the Johns Hopkins Hospital, in the service of Dr. Howard Kelly.

As all our means of diagnosis were exhausted without arriving at a conclusion, an exploratory nephrotomy was decided upon and this was done by Dr. Kelly.

Operation.—Before administering the anesthetic, the left ureter was catheterized and the catheter left in place. Ether was then given and with the patient lying over an Edebohls'[4] bag, the kidney was exposed and brought out onto the loin. There were no adhesions and externally the kidney appeared to be perfectly normal. By means of a gravity apparatus attached to the catheter, the pelvis of the kidney was now distended with salt solution and while the assistant controlled the hemorrhage by pressure on the pedicle, a longitudinal incision was made through the cortex in the line advocated by Brödel[5] (just posterior to the posterior border of the kidney; the line, along which the anterior and posterior branches of the renal artery meet and through which an incision severs the fewest possible vessels). The distention of the pelvis and calyces simplified their examination, as it kept the tissues from becoming blood-stained. A most careful search failed to reveal the slightest abnormality, either of the pelvis or the parenchyma. A liberal sized piece of the cortex was removed for microscopic examination, the kidney sutured with through-and-through stitches of fine catgut, replaced and firmly held in position by packing with iodoform gauze.

Convalescence.—The after-history was uneventful. On November 10, I again catheterized the left ureter and found that the kidney was excreting its normal proportion of urine. This

was still blood-tinged but of a much lighter tint than before the nephrotomy. Blood continued in the urine, in decreasing amounts, until November 27, 1902, when it completely disappeared and has not thus far returned. The patient's general condition since the operation has been excellent.

Pathological Report.—Microscopical examination of the tissue removed showed it to be perfectly normal.

We have then, in this case, hematuria, the cause of which remains a complete mystery. There was no bacteriological infection, for the urine was proven to be sterile on two different occasions. Calculus and tuberculosis were carefully excluded. There was no nephroptosis. There were no macroscopical lesions and no microscopical alterations in the portion removed. The bleeding did not cease because of atrophy, consequent upon the operation, as might be conceived, for a subsequent catheterization showed that the kidney was excreting urine in the same amount as before the nephrotomy.

Shall we then say that it was a case of hematuria from an anatomically sound kidney and thus admit that this can occur? With the idea of ascertaining what pathologic evidence there is in favor of the existence of a true idiopathic hematuria, I have examined the literature of the past twenty years. Fairly numerous reports of such cases occur and they may be divided into two groups—(1) those from the medical clinics and (2) those from the surgical clinics. The former are much the more numerous but as the diagnosis rests on negative findings and on the cessation after treatment, without the true condition of the kidney ever having been learned, such reports furnish no scientific evidence.

In order to prove that bleeding comes from a sound kidney, it is necessary to prove (1) that the hemorrhage is renal. This can be done, with certainty, only by the catheterization of the ureters. (2) The kidney must be subjected not only to exposure, with palpation, needling or even longitudinal incision, but there must also be a microscopical examination of a portion of the renal tissue. Even when this latter test is applied, it is conceivable that the part of the organ from which no specimen is taken may be diseased and the cause of the hemorrhage.

Excluding movable kidney, I have studied 19 cases reported under one or another of these headings. There are numerous others, as in the list reported by Harris[6], but these I have not included as there are obvious facts given, which might well account for the hemorrhage.

Most of these 19 cases have been cited time and again throughout the literature as proving the existence of hematuria from normal kidneys. Of how much weight is the evidence? They may be divided into two classes: (*a*) Those in which the examination has been macroscopical only; (*b*) Those in which the microscope revealed evidences of interstitial nephritis but which have been reported as cases of idiopathic hematuria because the author either disregarded or was ignorant of the fact that bleeding may occur in chronic nephritis.

That the macroscopical examination alone is insufficient, especially if the kidney is simply exposed and palpated, without an incision through its cortex, is, I think, evident when one considers how frequently are seen at autopsies, kidneys, externally apparently perfectly healthy but on incision found to contain a small stone, a general interstitial inflammation, a focus of tuberculosis, or more rarely a new growth.

In the cases reported by Anderson,[7] Broca[8] and Passet,[9] the kidney was simply exposed and palpated. In those of Durham,[10] Abbe,[11] Legeau,[12], Oliver[13] (case II), Guyon,[14], Loumeau,[15] Harris,[16] Rovsing[17] and Debesaques,[18] the organ was incised and carefully examined but not studied microscopically.

In the other group, microscopical sections were made and areas of interstitial nephritis of varying sizes were found. Such was the case in the reports of Sebatier,[19] Senator,[20] Oliver (Case I), Floderus[21] and McGowan.[22]

After excluding these cases there remain two unexplained, one reported by Klemperer[23] and the other by Schede.[24]

Klemperer's case was that of a male, aged twenty-two years, who had always been healthy and had no hereditary tendencies. A year before coming under Klemperer's observation, he suffered for three months with bloody urine, but this disappeared and he remained free from it for nine months. It then returned and a cystoscopic examination revealed blood coming from the left ureter. Except for the blood, the urine was normal. After the hematuria had continued for four months, nephrectomy was done. The whole kidney was carefully examined by the best authorities and pronounced absolutely normal. Five years later the bleeding had not recurred.

Schede's patient was a man, aged fifty years, who had had hematuria for several months producing marked anemia and baffling all attempts at explanation. After a suprapubic cystotomy the ureters were catheterized, the source of the hemorrhage learned and the kidney removed. It proved to be perfectly normal.

Is our case similar to these or was there a microscopical lesion of some unexamined portion of the kidney? The piece removed for histological study was relatively small and might easily have been from a portion of the parenchyma which was sound. The case was more carefully studied than were most of those cited as examples of idiopathic hematuria and nothing was found to account for the hemorrhage. Still, I would prefer to adopt the view, advocated by Israel[25] and Rovsing,[26] that there was a cause—an undiscovered one—rather than to assert that it is an example of bleeding from an anatomically sound kidney.

In view of the fact that there are thus far on record but two cases which apparently prove that hemorrhage may take place from a kidney which is not the seat of a pathological change, it would seem far better to me to put them aside as yet unexplained, than to admit into our classification a group such as has been mentioned.

THE PRESIDENT'S INAUGURAL ADDRESS.[1]

BY HENRY S. STEARNS, M.D.,

OF NEW YORK;

VISITING GYNECOLOGIST TO CITY HOSPITAL, CONSULTING SURGEON TO HOSPITAL FOR RUPTURED AND CRIPPLED.

I DESIRE first of all to thank you for and express my sincere appreciation of the honor you have conferred upon me by electing me to the high office of President of our time honored Society, the veteran of all the medical organizations existing in this great city to-day. And through all the many years of its existence, we can see a steady increase in its numbers and in the attendance at its meetings, until last year when our records show a larger average attendance than any of our contemporaries. As I recall the names of those on the list of my honored predecessors, a deep feeling of the responsibility of the office rests upon me, and it is only possible to promise that no effort of mine shall be spared to make the meetings of the coming year as interesting as possible, and to see that our efforts for the welfare of the profession and of the public shall suffer no diminution. Your retiring president has adminstered the office with such signal energy, tact and success, that in vacating the office he leaves the Society in the most flourishing condition it has enjoyed for many years, both as to the number on its roster of members, the largely increased attendance at its meetings, and the importance of the work accomplished by its committees.

The unusually large number of members added to our rolls during the year just ended is most gratifying, and allow me to explain some of the reasons why it is very desirable that this increase should continue until we have enrolled with us as nearly as possible every respectable licensed practitioner in the county. We may certainly with justifiable pride and without a gainsaying voice claim our organization to be the oldest and largest in the city; but to my way of thinking, this is far from being more than a most superficial view. There are so many of us who have the impression that the main function of the Society is to have presented to it once a month scientific papers for our instruction and entertainment and afterwards to have an opportunity for a half hour's social intercourse with our brother practitioners. But although this is an important part of our activities, we should have and do have much higher objects than mere personal benefit. If it were not so, we would be on a plane hardly higher than that of the trades unions. Our work has always been and must, as time goes on, look more and more toward the benefiting of the public where its needs and our acquirements coincide.

Would that I could impress upon all of you more vividly the importance and value to each one of us personally of the work done by your Comitia Minora and other standing committees. Let me emphasize that far the greater part of the work done by the medical profession in this city for the suppression of illegal and criminal practitioners and for the amelioration of conditions inimical to the public health is done by the New York County Medical Society. As you all will admit, the mere inertia of numbers has an enormous effect upon public policy, and therefore certainly the more nearly we include all respectable practitioners among our members, the greater becomes our influence for good in these two important objects. And so I would urge upon you all to persuade your professional friends and acquaintances who are not already members to become so. The effects of a largely increased membership would be promptly evidenced not only by much more efficient results whenever we endeavor to influence the authorities on matters pertaining to the public health, but also by increased consideration for our opinions and recommendations, by the courts and legislature.

To cite an example of this, on the tenth of last month, in the city courts, the maximum fine for the sale of impure milk was imposed on no less than fifty dealers. This was very directly the result of the work of our Milk Commission. Its bringing so forcibly to public notice of the deplorable quality of much of the milk sold in this city, aroused the health authorities to much more energetic action than they had shown for some time. It is doubtful if the Commission would have had anything like this consideration shown it and its recommendations, were it not that it had the backing of this, the largest medical society in the city. Here we have an evidence of the success attending the utilization of the weight of numbers.

Let us examine the other side where our numbers and influence, large as they are, seem still insufficient to obtain results alike important to

1 Read at stated meeting of the Medical Society of the County of New York, held in the New York Academy of Medicine, Monday, November 28, 1904.

the profession and the public. Instancing this is the unsuccessful attempt of the Legislative Committee of the State Society to obtain from the Legislature the enactment of a new statute defining, more exactly than had been done before and more in accordance with present day needs, what in the courts shall be the interpretation of the term "practice of medicine." Had our numbers been considerably larger, so much weight would not have attached to the representations of the faith curists and others when the bill came up for consideration in committee in the legislature, and from which I believe it never emerged. Again, I ask, can anyone doubt that the larger the number of members we have back of such requests and recommendations to the legislature, the more likely is the profession to obtain the enactment of a statute which will permit of our arresting, fining, and imprisoning imposters appropriating the title "Doctor" to deceive those coming to them for medical advice, no matter whether they merely prescribe or actually give medicine, or some other form of treatment. And also for the punishment of those far more dangerous persons who are actually licensed practitioners but who from the character of their work in performing criminal and illegal operations, are certainly morally criminal to the highest degree, but whom the law at present actually protects to a certain unnecessary degree, by placing so many requirements and restrictions as to the form and manner of having evidence admitted, that it is only with extreme difficulty and at great expense that a conviction can be obtained.

In addition to this moral effect of increased numbers, there will be the very potent advantage to your Board of Censors of having a larger fund to disburse in these prosecutions for the suppression of criminal and illegal practice and quackery. At present and for years past, we have been devoting every dollar of our surplus funds to this end, and you may rest assured that many times our annual appropriation could be used to advantage. After five years' work on the Board of Censors, I feel justified in the assertion that, taking into account our limited funds, we have attained the highest point of efficiency possible in the work accomplished by your Board of Censors and counsel. Do not misunderstand me as saying we are doing all that should be done; in fact, what we are doing is little more than an indication of what we ought to be able to do if we only had the sinews of war. Your counsel is so eager to prosecute this work that hardly a meeting of the Board occurs but he has to be warned that the limit of possible expenditure will be overstepped if he do not lessen the number of prosecutions. It has been asked time and again by the daily press why with thousands of charlatans in the city, and numbers of them openly advertising in the papers, the County Medical Society does not suppress the larger part of them. As already indicated, the answer to this criticism is our lack of funds, not only to defray expenses of a prosecution after an arrest has been made, but also the usually much greater expense involved in the collection of sufficient evidence to obtain an indictment. A larger fund is imperatively needed if we are, even in a moderate degree, to live up to the expectations of the public in this line of work. It has been suggested many times that our prosecutions against offenders are by right the duty of the District Attorney's office; but while this branch of our municipal government gives us a certain amount of encouragement by lending its countenance to our efforts and in addition an occasional very small modicum of actual tangible assistance, nevertheless the main burden of the work devolves upon us, or a prosecution would rarely be started and still more rarely carried through to a conviction.

Besides the lack of sufficient funds for a satisfactorily energetic prosecution of this work, and never in our history have more brilliant results been obtained in our legal department than during the last year, there stands squarely in the way of our success the lack of a statute defining the "practice of medicine" more exactly in accord with the present ideas of the public and the profession than that now in existence. Other States, notably Michigan, are decidedly in advance of us in this particular. Some of the suggested changes which seem particularly worthy of your careful consideration are:

1. Adding a provision to the present law defining more clearly the power of the Regents, to revoke the licenses of physicians for unprofessional conduct and providing for a form of trial before the Regents for the revocation of licenses.

2. A re-registration of physicians. It is a notorious scandal that many quacks are now practising under dead men's diplomas, and with the present medical register of this county containing nearly fifteen thousand names, it is getting to be increasingly difficult to identify practitioners with any given license. There should be inserted a provision in the proposed law requiring a registration with the Secretary of the Medical Society of each county.

3. The regulation of advertisements, following the lines of the Michigan law.

4. The reenactment of a comprehensive definition of what constitutes the practice of medicine similar to the definitions in many states, the idea being to so define the practice of medicine as to make it apply to all those who diagnose and attempt to heal by any method whatsoever.

5. So changing the penalty of practising medicine as to make it a misdemeanor. At present, for the first offense we cannot impose both fine and imprisonment. Neither can a fine be over $250. This ought to be changed so as to make it a misdemeanor, and thereby carry with it a fine up to $1,000 and imprisonment up to one year.

6. Inserting a provision in the medical law requiring all advertising medical concerns to post

on their signs the names of the practitioners and in the office of each practitioner the name of the person so practising. There is a similar provision in the dental law, and there should be one enacted for the medical law.

7. The ambiguity in the present law prohibiting the use of the title doctor should be cleared up. The words "without having legally received a medical degree" should be so worded as to make it certain that the meaning is "without having legally received the medical degree in the State of New York." The use of the title of doctor by barbers, chiropodists, etc., should be distinctly prohibited.

8. The agents of the Medical Society should be made peace officers under the statute, by enabling them to make arrests similar to the powers conferred upon the agents for the New York Society for the Prevention of Cruelty to Children.

9. The repeal of the provision permitting fines to be returned to the Society as a result of prosecutions.

But a united profession in the State is an absolute necessity before we can expect to wield influence enough to convince the legislature that our requests for any such modification of the statute would undoubtedly be for the furtherance of justice and the public welfare. It was hoped that this unity would have materialized ere this, naturally and quickly, through the amalgamation of the two largest medical organizations in the State, viz., the New York State Medical Association and our own New York State Medical Society, for it is the particular province of these two to prevent the invasion of the medical laws and suppress the particular branch of vice under consideration. The union of these two bodies into one compact body could not fail to result in a largely increased influence both with the courts and the legislature, and at the same time allow the appropriation of much larger sums for the work of the legal department.

After so much has been said and written about the origin of the New York State Medical Association over twenty years ago, it would be a waste of time to thrash over that ancient history this evening. But whatever our reasons may have been for the abolition of the Code of Ethics as an integral part of our Constitution and By-Laws, let me say that with one or two exceptions I look upon this venerable and much discussed document as a just exponent of the moral obligations of the physician, and that the further we depart from the spirit of its teachings the lower shall we fall from that high moral plane upon which the practice of our profession should rest. This action of ours, in abolishing the code, has since received the seal of approval by many other States following in our footsteps, and finally two years ago the wisdom of our action was tacitly admitted by the American Medical Association, at its annual meeting, making the code only advisory and not as before obligatory; besides making such internal and external changes as altering the name to "The Principles of Medical Ethics" and abolishing entirely one clause to which we originally took serious objection.

Possibly the following short synopsis of the amalgamation proceedings may be of interest: At the annual meeting of the State Society in January, 1902, a committee of five was appointed to confer with an equal number representing the State Medical Association, for the purpose of formulating a plan which should have for its object the reorganization of the regular profession of the State into a body in affiliation with the American Medical Association. This committee to report at the annual meeting in 1903. On February 7, the Executive Board of the State Association appointed a similar committee, and on March 19 the first joint conference was held. But little of real importance was accomplished during the year in spite of several joint conferences, because the old code was still an integral part of the Constitution and By-Laws of the American Medical Association and therefore binding on the State Association, and at the same time and quite rightly our committee declined positively to subscribe thereto. At the annual meeting of the State Society in 1903, our committee made a full report and was continued.

The deadlock between the two committees continued until on May 7, 1903, the American Medical Association, at its annual meeting held in New Orleans, took radical action and removed the obstacle preventing the unification of the two State organizations by adopting an instrument called "The Principles of Medical Ethics," and in the resolution this document was specifically termed "A Suggestive and Advisory Document." It was also stated in these resolutions that "The Principles of Medical Ethics" have been substituted for the "Code of Medical Ethics." Furthermore, the article in this instrument named "The Duties of Physicians in Regard to Consultations" has only this to say as to with whom we should consult. "The broadest dictates of humanity should be obeyed by physicians whenever and wherever their services are needed to meet the emergencies of disease or accident." Thus the deadlock was broken and on October 1, 1903, the State Association appointed a committee of five "empowered to do whatever was necessary and expedient to bring about a union in a just and equitable manner." Following this, a special meeting of the State Society was called for October 13, 1903. The meeting was held in this hall and by unanimous vote the conference committee was given powers equal to and commensurate with those given by the Association to its committee. This action pledged both sides to abide by whatever was decided by these two committees in joint conference. They met promptly and began their arduous and responsible task. They drew up a modified constitution and by-laws for the State Society and drafted

an act to authorize the consolidation of the Medical Society of the State of New York and the New York State Medical Association. This act was promptly passed by the Senate and Assembly, and was signed by the Governor on January 21, 1904. This act required that all the corporations involved should vote a majority of its members in favor of the consolidation; that is practically the different organizations in the various counties. All of the active county societies met promptly and ratified this action. On properly verified presentation of these actions to the Supreme Court, the latter was authorized by the act to make an order for the consolidation. When, however, this presentation was made, some objection developed from the Onondaga County Association, and the Court decided that the vote in the case of the Association had not been taken in accordance with the State law requiring the notification of individual members where a transfer of property was involved, and in consequence decided not to grant the order for consolidation. This made necessary a change in the By-Laws of the Association, which could only be accomplished by having the alterations presented at an annual meeting and voted on for adoption at the next succeeding annual meeting. As a result, the necessary changes in the By-Laws were offered at the annual meeting of the State Association held here last month, and they can not come up for adoption until the meeting in October, 1905. At the annual meeting of the State Association just held, the following resolutions were offered at the instance of its present president and unanimously carried, viz.:

Resolved, That the unfortunate delay in the efforts of the State Medical organizations to amalgamate, due to no fault of either party, is a source of grievous disappointment to this Association, and

Resolved, That it is the unalterable desire of the New York State Medical Association that harmony and good fellowship should prevail throughout the entire profession of the State, and to that end this Association pledges itself to endeavor to secure the union of the two State organizations until that much desired end shall have been accomplished.

Apparently, however, the accomplishment of the wishes here expressed was hardly aided by the fact that they dismissed their conference committee. But there may result no delay from this cause if a new committee is appointed promptly next fall, and I am glad to be able to inform you that assurances from those high in the counsels of the Association leave small doubt that the same committee will then be reappointed.

In closing this summary of the most recent developments in the efforts for consolidation, there remains only to say that the State Society and all of the active County Societies have absolutely honored all pledges given in joint conference by their committee, and now as far as the County Medical Society is concerned, we can only wait until the Association is able to carry out its part of the agreement. I feel very keenly the sentiment of disappointment over this delay and believe it to be a well-nigh universal one in our Society. If there are any cherishing different feelings, it has not been my fortune to come in contact with them.

And so let us enter on this new year of work with a fixed determination to do all in our power to foster a kindly feeling with our brethren in the Association, that when the amalgamation has been accomplished, there may be no serious internal dissensions, and that we may then present a united front in our combat with vice and in our efforts to obtain from the lawmaking powers changes in the statutes enabling us to proceed more promptly and effectively against charlatans and criminal practitioners.

I take pleasure in announcing the following committees for the year of 1904-05:

Committee on Discipline.—John P. Munn, M.D., Chairman, 18 West Fifty-eighth Street; Edward D. Fisher, M.D., and James D. Newcomb, M.D.

Committee on Hygiene.—Henry G. Piffard, M.D., Chairman, 256 West Fifty-seventh Street; Walter Bensel, M.D., and Smith Ely Jelliffe, M.D.

Committee on Audit.—John C. Minor, M.D., Chairman, 115 West Seventy-third Street; David M. Marvin, M.D., and Cornelius G. Coakley, M.D.

Milk Commission.—Edward K. Dunham, M.D., Chairman, 338 East Twenty-sixth Street; Rowland G. Freeman, M.D., Secretary, 205 East Fifty-seventh Street; Walter Lester Carr, M.D., Henry Dwight Chapin, M.D., Abraham Jacobi, M.D., Alexander Lambert, M.D., William P. Northrup, M.D., William R. Park, M.D., George M. Swift, M.D., Joseph E. Winters, M.D.

HYSTERECTOMY AND THE GENERAL HEALTH.

BY EUGENE COLEMAN SAVIDGE, M.D.,

OF NEW YORK.

When the choice is hysterectomy or death, hysterectomy is the only way to general health. And we should view such an operation in its best phase. The same obligation is upon us as upon the surgeon amputating a hopelessly infected leg. Bound by all the humanities to minister to the mind perturbed as well as saw off the leg, his optimism should dwell upon the mechanical perfection of the artificial limb. He should minify the increased susceptibility to hemorrhage, apoplexy, and the other disabilities following so great a change in the statics of the circulation.

Similarly, all that follows an "only alternative" hysterectomy is not to be weighed with the life it confers. It is worth the price without haggling. But there are cases in which the wisdom of a hysterectomy is debatable. With these latter I shall deal, understanding by a "debatable hysterectomy" the removal of Fallopian

tubes and ovaries, as well as the uterus, in patients who might be restored, more or less completely, by other methods. I distinctly exclude cases of hysterectomy in which a portion of the ovary is retained.

The following will express my convictions on this subject elsewhere recorded:[1]

"My clinic at Roosevelt Hospital ten years ago brought me a large number of patients from whom both ovaries, and frequently the uterus, had been removed by operators in various parts of the world. In some patients ten years had elapsed since the operation. The majority, however, were recent cases. This time corresponds with the highest tide in activity in complete salpingo-oophorectomy; never before, and not since, has like opportunity for postoperative study come to the clinic.

"My conviction grew that a portion at least of ovarian tissue is essential to a woman's well-being. Its entire removal brings psychical and material changes which result in very definite modifications in the nutritive, renal, hepatic, arterial and cardiac functions. These take her out of the gynecological field into that of general medicine, and the connection between cause and effect is lost; but nevertheless the patient's utility and life are thereby curtailed. This conviction is as strong as a conscientious and purposeful study of ten years, with ample opportunity and an open mind, can make it."

These convictions hold notwithstanding the undeniable good wrought by these operations. Hollow cheeks have rounded out and bloomed, pain-bent frames have straightened, and bed-ridden invalids have been restored to active life by hysterectomy. A mild sensual sense and power of orgasm have been retained. A degree of worldly prosperity has even come in the freedom from menstruation and child-bearing. Indeed, when we consider the enhanced quality of the naval orange from which the reproductive organs have been removed; or the increased beauty and cleanliness of the spayed lily from the florist, or the steady utility of the prepared horse over the restless stallion, or, again, the increased lard production in swine altered for the market, and then return to the contrast between the pain-bent, hemorrhagic invalid, transformed by hysterectomy into the round, well-staunched woman.—capable of a full month's work—we might be pardoned for reaching a superficial, but fatuous, verdict.

Hysterectomy enhances another capacity in a woman by twenty-five per cent. The calculation, as some of my confrères will remember, was made by an aged woman with saintly pose, distributing flowers and tracts in a certain women's ward. Her solicitude for young women without organs led to the discovery that, as a life-long procuress, she was seeking such cases with an avidity equal to that of an ornithologist after his *desiderata*.

Unquestionably, the severer the call for hysterectomy, the longer the suffering before it, the greater the contrasted benefit after it. And as Esau bargained his birthright for creature-comfort, so many of us would willingly quell instant pain at the discount of future good. In certain classes of the community, every "debatable" hysterectomy is such a discount.

The operation discounts effective longevity. For not only are all the circulatory susceptibilities noticed in the case of amputations relatively involved, but there is also a direct physical after-result. There will be noticed a mixed condition of arterial tension, venous engorgement and muscular relaxation, followed later by renal insufficiency. Nearly a decade ago I wrote upon this susceptibility of women with pelvic trouble —"with almost a chronic priapism of the pelvic organs, liver and spleen," as I then called it—to increased vasomotor pressure, and subsequent renal insufficiency. Professor W. H. Thomson, in a recent issue of the *Medical Record*, from quite another field, has reached a like conclusion regarding the order of the conditions; that the increase in blood-pressure precedes and perhaps causes the ensuing Bright's disease; that, possibly, through certain altered vaso-motor relations, adrenalin is liberated in the organism to cause the primary increase of blood pressure. Perhaps changes in the statics of the circulation release the adrenalin, or, as I now advance tentatively, perhaps an analogous super-skill of remaining function—like the acute hearing of the blind, the lip-reading of the deaf—ensues when the reproductive function is suppressed. There must unquestionably be some compensatory relation between foliage and fruit, so to speak, in the human plant.

Or, perhaps, the nerve stumps, acting on the sympathetic system, throw the organism into an unrelievable tension, as a soldier stands at attention before a superior officer. Tension is the physical call for the reproductive act; tension muscular, nervous and psychical, followed by equivalent relaxation.

But whatever the speculative cause, the result is the mixed condition above described, followed by renal insufficiency and a material shortening of life.

There is another side to the question with an equal bearing on effective longevity. Let us leave out of the question the few who have been left by "debatable" hysterectomy obvious physical and nervous wrecks, those with melancholia, those who commit suicide; and take the synthetical view of the vast majority who, superficially, do well, who are improved economical animals during the period of muscular activity, producing more flesh, scrubbing more days in the month, having, generally, a steadier utility in all material departments. Such cases furnish the precise analogue with the navel orange and

[1] Extract from views presented to the Sixth International Congress of Gynecology, Madrid, 1902, through Dr. A. Palmer Dudley.

draught horse. If such patients had neither mind, nor soul, nor future, and could be plucked and utilized at the proper moment, as a vegetable is ripened or a hog is fattened for the market, they would prove hysterectomy to be "the one thing needful," to adapt them to their environment. And as the criminologist has urged the spaying of criminals for the safety of society, so might the sociologist view hysterectomy on all the pauper classes as blessing the individual and immensely conserving national health. View the vast hysterectomy statistics of some of our French confrères in this light, and in the light of the avowed desire for spaying with many of the women of the town—for commercial ends. But even this is debatable, considering the occasional gem from the muck.

Even in these stolid ones of the community, however, may be noticed the following differences after a hysterectomy: a comparatively lusterless eye, a roughened voice and an increased hair growth; a flattening, or a fattening of the breast at glandular expense; an increase of fat, a devitalization, or a defeminization, or a hebetudinization, so to speak; a changing, as from the high-stepper to the cart-horse; from the alertness of the city-bred to the hebetude of province, where nerve stimuli are few and slow and response thereto similar. It is a wiping out of zest, spirit, and pride of port.

These objective results are patent to the superficial observer. Their significance, however, is more difficult reading. We are helped in this reading by the almost spectacular restorations possible in those cases that I have called "the self-obliterated feminine element." These cases, as elsewhere elaborated, represent the gradual stamping out in function of the selective cells of sex in women from twenty-five to forty years, who show diminished menstruation, loss of sensual sense and power of orgasm, with an increase of weight, roughening of skin and voice, and a growing lithemia and hebetude. As a cause, or a result, the obliteration of the feminine element in the individual almost rivals the work of the knife in its completeness. Note that in these cases the navel orange, draught horse, lard-producing analogy and capacity are not lost. But what goes is, reproductive capacity, spirit, initiative, outlook—in other words, the "house of the mind," without which there can be no effective longevity.

It is only to those color-blind to the possibilities of female life, aside from reproduction, that these matters will seem unimportant. For efficient longevity is entirely a class matter. There can be none of it after the time of muscular activity with those falling in my biological classification.

Less far afield may seem the question of modified conjugal destiny by hysterectomy, and the bearing of thwarted destiny upon health and spirit. Again, it is easy to realize the bearing on life-conduct, thrift, future-planning and morality, of a knowledge to a woman that she is hopelessly barren. The special psychology of a woman gives great possibilities for anguish here. She may have avoided children until she realizes her barrenness, then maternity becomes the sole yearning of her life. (This is so well shown in the converse found in one of the writer's cases, where, after six years of supervision, sterility was overcome, to the patient's great joy. Returning from a brief vacation in Europe I found her bleeding from an abortion procured during a sudden change of desire—the impulse of the moment outweighted the yearning of years.) Although sterility may persist without hysterectomy, the sustaining quality of hope remains. That any one to whom the physical destinies of a human being are entrusted should ignore so important a value, seems as strange as the limitation of the color-blind.

This is why our subject demands not only the separation of the "only alternative" from the "debatable" hysterectomies, but also the consideration of the class of patients operated upon. I am almost tempted to add that the surgeons themselves have varied ranges of vision.

And right here may be struck what I now call —at the recognized risk of being called fanciful —a distinctively American note in gynecology. I make bold to dogmatize that there is a necessity for a marked difference in deduction and procedure in dealing with American women. The point is as subtle as an instinct, but I think I can reason up to it.

Our gynecological statistics are made up from hospital work in congested centers, or are imported from Europe. Tenement house experience and statistics from European peasantry are reliable enough on the "navel orange, draught horse, lard-making classes," but absolutely incomplete with regard to the women of the so-called "plain people" of America, however lowly their station. While those nearer the top of the social fabric in all countries show fewer variations, the distinguishing difference between an American woman of humble station, and even an English woman correspondingly placed, is this: The American woman has a more highly-evolved nervous sytem, with its accompanying nervous vitality. If you question it, contrast an American farmer's wife whose son may be President in her hopes, with an English butler's wife, who is resigned and content in training posterity for similar station. The difference in the American woman has grown principally from an inherited perception of the chance to rise. Knowledge of opportunity has stimulated search for it, and from this has been manufactured—out of European material, it is true—that restless, alert, aspiring nervous system, with its initiative, which has had such a bearing upon our national life. It is a nervous system, difference, a spirit difference, which the ethnologist can spot instantly in a cosmopolitan gathering.

Here is where "debatable" hysterectomy works most harm, and where we get the sharpest contrast. I place the matter far above sensuality or brothel effect. For that energy brewing in a woman's mind, in many a cabin in the wilds, has been potentially the success which the world sees a generation later in the great centers. She may even have borne her last child, and be thenceforward sterile; she may appear restricted and unembellished, as she comes up to the great man of the city for his *ipse dixit*—nevertheless the American woman is not the same as the clinic woman. As a class, she has latent capacities and a promise of effective longevity that we jeopardize by the "debatable" hysterectomy, with its spirit-robbing, pride-abasing, zest-exhausting, devitalizing results.

And this is my "American idea" in modern gynecology.

66 West Fiftieth Street.

AN ANALYSIS OF TWENTY-FIVE CASES OF STRANGULATED HERNIA TREATED BY OPERATION.[1]

BY GEORGE TULLY VAUGHAN, M.D.,

OF WASHINGTON, D. C.;

ASSISTANT SURGEON GENERAL, U. S. P. H. AND M. H. S.; PROFESSOR OF SURGERY, GEORGETOWN UNIVERSITY, WASHINGTON, D. C.

IN 115 operations for inguinal and femoral hernia I have had 25 cases of strangulated hernia requiring operation. Care has been taken not to include simple incarcerated hernia, but only those cases in which the intestine was not only incarcerated but the circulation of blood was so obstructed as seriously to threaten, and in several cases to destroy, the integrity of the intestine.

As to variety, five were femoral and 20 were oblique inguinal. Twenty-three were on the right side—only two on the left. Hernias are much more common on the right than on the left side. In my list of 104 inguinal hernias, 69 were on the right and 35 were on the left side. Of 11 femoral hernias, nine were on the right and only two on the left side, but when we consider the 25 cases of strangulation we find all (5) the femoral, and 18 of the 20 inguinal hernias on the right side. It would seem from these few statistics that strangulation is more apt to occur in the right than in the left-sided hernia. I had no case of strangulated direct inguinal hernia. According to the relation of the hernia to the peritoneum there were 11 congenital, the funicular process remaining open, six acquired and one of the infantile variety in 18 cases, seven not being considered—the five femoral hernias and two inguinal in which the variety was not stated in my notes. The case of anatomically infantile hernia is the only case I have seen. The patient, No. 6 in the table, was a hard drinker, and had had a hernia all his life. On incising the coverings of the hernia, three distinct layers of peritoneum were divided before reaching the intestine—the first two layers forming a pouch above, which was continuous below with the tunica vaginalis testis.

These statistics would indicate that congenital is about twice as apt to become strangulated as acquired inguinal hernia. There were two cases of properitoneal or interstitial hernia—cases Nos. 15 and 24 in the table. In No. 15, a boy thirteen years old, the hernia consisted of a mass of gangrenous omentum tightly wedged in between the transversalis muscle and transversalis fascia above the internal ring. The funicular process was open. No. 24 was a youth, aged eighteen years, who stated that the hernia had suddenly appeared about forty-one hours before he was operated on. About three inches of small intestine were found wedged in between the transversalis fascia and transversalis muscle, and slightly protruding through the external ring. These are the only cases of interstitial hernia I have seen in 104 inguinal operations. Coley reports only seven cases in 937 operations.

Only one of my cases, No. 14, was complicated with an undescended testicle. My youngest patient was six weeks, and the oldest seventy-seven years old. Four patients were between ten and twenty years of age; two between twenty and thirty; four between thirty and forty; five between forty and fifty; three between fifty and sixty; two between sixty and seventy, and four patients between seventy and eighty years of age. The ages of the fatal cases were as follows: Two seventy-seven, one each sixty, fifty-two, fifty-one and forty-one years old.

Site of Constriction.—Often it is impossible to determine the exact point between the internal and external rings which causes the strangulation and sometimes it seems to be caused by constriction exerted along the entire inguinal canal. In sixteen cases in which I was able to determine definitely the point of greatest constriction, in eight cases it was at the external ring, in seven cases at the internal ring, and in one case in the abdominal cavity—probably volvulus (Case No. 8).

Contents of Sac.—In the large majority of cases (19) the sac contained small intestine alone, and in every instance in which small intestine was found in the sac and the portion identified—11 in number—it was found to be ileum. In one case the contents were two loops of small intestine (Case No. 18); in one, small intestine and omentum; in one, small intestine and undescended testis; in one, large and small intestine and omentum; in one, large intestine (sigmoid flexure) only; and in two, omentum only. In 11 cases dark or turbid fluid—sometimes blood clots—was found, and in these cases strangulation had existed from two hours to ninety-six hours; in eight cases over six hours, and in only three cases less than six hours.

Venous thrombosis is the mesentery, ecchymosis, or hematoma of the intestinal wall or mesentery were found in 10 cases, and while it

1 Read at the meeting of the Medical Society of Virginia, October 18 to 21, 1904.

is admitted that venous thrombi may be caused by constriction alone, yet it is believed that they are caused most frequently by taxis. In two cases the intestinal wall was rough and bruised, and in one a large hematoma was found in the intestinal wall, and was treated by incision evacuation and suture.

In nine cases the contents of the sac were gangrenous, three of the omentum only, and six of the intestine, and in four of these there was what is usually called general peritonitis.

In the gangrenous cases the time during which strangulation had existed was as follows:

In one case, thirteen days; in one, nine days; in two, four days; in two, three days; in two, one day; in one, four hours. In the last case the gangrene was probably caused by volvulus in the abdominal cavity—there was not sufficient constriction at the rings or in the sac to cause such a complete strangulation—Case No. 8.

Symptoms.—Besides the physical signs the two most valuable symptoms of strangulated hernia are *pain* and *vomiting*. Pain existed in every one of my cases, but it varied in character, duration and locality. It is often described as sickening, sometimes as griping, and usually lasts until the constriction is relieved or gangrene sets in. While usually felt most severely in the neck or immediate vicinity of the hernia, the pain may be general in the abdomen or the point of maximum intensity may be quite distant from the hernia. In Case No. 13, a right strangulated femoral hernia, the patient complained of most pain in the left hypochondriac region, and for sometime could not be persuaded that the pain came from a small swelling so far away, which was just a little tender, and which he had had off and on for thirty years, so that twenty-four hours of valuable time were lost, and a gangrenous bowel was the result.

Vomiting occurred in 20 of the 25 cases, nausea without vomiting in two, and neither nausea nor vomiting in three. In four cases the so-called stercoraceous vomiting occurred—that is, the contents of the small intestine were ejected, and as would be expected, strangulation had existed a long time—in two cases, four days; in one, nine days, and in one, thirteen days. The last two cases ended fatally.

Complete notes of the pulse and temperature were not kept, but enough was seen to justify the conclusion that they are unreliable as affording evidence of the condition of the bowel. For example, in Case No. 9, after strangulation had existed nine days, the pulse was 68 and temperature 96° F., whereas in Case No. 11, after strangulation had existed for the same length of time the pulse was 120 and temperature 98.6° F.

Treatment.—Taxis was not advised nor practised, except when insisted on by the patient after having the dangers pointed out. The danger of returning a bruised, ruptured or gangrenous intestine or omentum, or a loop of intestine with the constriction unrelieved is not to be compared with the safety of an open incision with inspection of the contents of the sac so that they may be dealt with according to the conditions found. Occasionally patients are seen who prefer death to an operation, as in one of my cases, an old lady, with a strangulated femoral hernia. The probable happy outcome of an operation and the inevitable fatal result without an operation were explained to her, but she deliberately preferred to die, and did so within a week.

In all of my cases, except three, after attending to the contents of the hernial sac, some operation for radical cure was performed. Of the three exceptions, two were cases of peritonitis, in which it was thought best to provide for drainage, and the third did not survive the operation. After examination of the hernia, with sufficient gentle manipulation to determine its condition, the operation is performed.

In inguinal hernia an incision is made as in Bassini's operation for radical cure, exposing well the external abdominal ring and the upper part of the hernial sac. The sac is then opened and the contents examined, after which the aponeurosis of the external oblique is slit up, opening the inguinal canal, and thereby relieving the constriction, unless it is situated at the internal ring or in the abdominal cavity. The contents of the sac are then treated according to circumstances. All constriction having been relieved the intestine is pulled down until the effect of the constriction on the bowel can be seen, as the pressure at this point is sometimes so great as to cause an indentation with damage to the bowel or even a perforation, especially in femoral hernia. If the intestine is of doubtful vitality it is covered with cloths and kept wet with physiological salt solution for from fifteen to thirty minutes. If the circulation returns, as shown by the red color, the bowel is restored to the peritoneal cavity, but if the circulation fails to return, resection is at once performed and the ends of the bowel reunited with sutures or button. A few gangrenous spots limited to small areas may be treated by turning them in with sutures or by telescoping a portion of the bowel, so as to cover and reinforce the damaged part and fixing with sutures.

The formation of an artificial anus with or without resection of the intestine must not be done in any case in which the patient's condition will permit resection with immediate reunion, since Gibson's statistics show a mortality from the former, just double that which results from the latter operation. In every case in which the patient's condition will permit an operation for the radical cure is performed.

In femoral hernia the incision is made from above downward and inward, crossing Poupart's ligament at an angle of about 45 degrees, and extending over the hernia. Poupart's ligament is divided whenever it is found necessary to do

so. The subsequent steps so far as treatment of the hernia is concerned correspond with those already given for inguinal hernia. As far as I have been able to ascertain, the results of the operation for radical cure in strangulated cases are as satisfactory in every way as those performed at other times.

Mortality.—There were six deaths in 25 operations: *Case 6* was a hard drinker, had a fatty liver and died of delirium tremens on the fifth day after operation. *Case 7* was a woman, aged seventy-seven years, who had suffered from strangulation thirteen days, and had an incipient general peritonitis when the gangrenous intestine was resected. She died of peritonitis forty-eight hours after operation. *Case 9* was a man, fifty-one years old, who had had a right inguinal hernia about forty years, but he stated that he had not been troubled with it for more than a year. At the time of operation he had been suffering with intestinal obstruction nine days, and was very weak. No sign of hernia could be found by examination externally, but laparotomy revealed a knuckle of ileum which was little more than a Richter's hernia, having entered the internal abdominal ring just far enough to produce complete obstruction and become strangulated. The patient died on the table apparently from exhaustion as soon as the hernia was reduced. An interesting phenomenon in the form of dynamic ileus was observed in this case—the intestine for fully 10 inches below the strangulated portion being contracted into a small cord completely obliterating the lumen so that water would not run through. There seemed to be a tonic contraction of the circular muscular fibers which remained in that condition after the specimen had been removed from the body and placed in preserving fluid. *Case 11* was a woman with a right femoral hernia which had been strangulated nine days and general peritonitis had set in. The gangrenous intestine was resected and a Murphy button used, but death occurred fourteen days later from peritonitis. *Case 13* was a man, aged sixty years, whose death was caused probably by his own obstinacy in not permitting an operation sooner. He had gangrene of the intestine from three days of strangulation with numerous mesenteric thrombi and beginning general peritonitis. Nineteen inches of intestine were resected, but death occurred four days later. Necropsy showed general peritonitis and gangrene of three feet more of intestine. There may have been an arterial embolism in this case.

Case 22 was a feeble man, aged 77 years, inmate of an insane asylum, who had had strangulation of a right oblique inguinal hernia for eight hours, and had been treated by taxis. Three feet of ileum, almost black, were found in the sac, with numerous large thrombi in the mesentery. Death occurred on the fourth day from toxemia or exhaustion. No peritonitis.

There were six cases of resection of gangrenous intestine, with three deaths, all from general peritonitis, which existed at the time of operation.

Reviewing the histories of these fatal cases it is almost certain that with one exception, Case 6, a timely operation would have saved the life of every one of the patients. It may be of interest to show the mortality (1) in general, (2) when gangrene or general peritonitis was not present, and (3) when gangrene or peritonitis was present.

Operations for strangulated heria, 25; deaths, 6; mortality, 24 per cent.

Cases in which the contents of the sac were in good condition (though some of these had thrombi in the veins and damage to the intestine), 16; deaths, 3; mortality, 18.75 per cent.

Cases in which the contents of the sac were gangrenous or general peritonitis existed at time of operation, 9; deaths, 3; mortality, 33 1-3 per cent. Six of these cases were resection of gangrenous intestine and three of removal of gangrenous omentum.

At Johns Hopkins Hospital from 1889 to 1899, there were 64 operations for strangulated hernia, with 19 deaths, a mortality of 29.68 per cent.

Cases in which the contents of the sac were in good condition, 48; deaths, 4; mortality, 8 per cent.

Cases in which the contents of the sac were gangrenous or general peritonitis existed at the time of operation, 16; deaths, 15; mortality, 93.75 per cent.

Erdmann reports 8 operations for gangrenous intestine or omentum, with 4 deaths; a mortality of 50 per cent. Six of these were resection of the intestines, with two deaths; one removal of gangrenous omentum, with one death, and one formation of artificial anum, with one death.

Horwitz reports 43 operations for strangulated hernia, with 15 deaths; a mortality of 34.88 per cent. Three of these were resections of gangrenous intestines, with two deaths; mortality, 66.66 per cent.

Coley reports in 1,063 operations for hernia, 17 operations for strangulation, with two deaths. One resection of gangrenous intestine resulted fatally.

Gibson collected from the literature, from 1888 to 1898, 226 resections of gangrenous intestine, with immediate reunion, having a mortality of only 26 per cent., and in 63 cases in which the Murphy button was used, the mortality was even less, only 22 per cent.

This is a much smaller mortality than that of any of the operators here quoted, and is probably a little more favorable than would be the statistics of *all* cases operated on, were it possible to collect them. It is well known that the successful is much more apt to report his cases than the unsuccessful operator, so that many failures are never heard of, whose sum total added to those published would materially increase the mortality. This is true of operations for other troubles beside strangulated hernia.

THE SIGNIFICANCE OF PUS IN THE NOSE, WITH SPECIAL REFERENCE TO THE AFFECTIONS OF THE ACCESSORY SINUSES AND THEIR PROPER TREATMENT.[1]

BY GEORGE L. RICHARDS, M.D.,

OF FALL RIVER, MASS.;

OTOLOGIST AND LARYNGOLOGIST TO THE FALL RIVER UNION HOSPITAL; FELLOW OF THE AMERICAN OTOLOGICAL SOCIETY; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY, ETC.

Until within a comparatively short time accurate diagnosis of the affections of the accessory sinuses of the nose has been unknown. With the development of nasal surgery as a specialty by itself came the more thorough study of the anatomy of the air spaces of the head, and finally the working out of a new pathology and a rational treatment for the affections of these sinuses, which are responsible for many a headache, and many a pain, and many a nasal discharge which were formerly classed under the vague heading of neuralgia or catarrh.

The treatment of these affections has grown from a mild conservatism to an extreme radicalism, and is at the present time still in a transition stage. The last word or the final treatment in regard to them has not yet been settled upon.

The accessory sinuses of the nose consist of the large maxillary antra, one on each side; the two frontal sinuses; two sphenoid sinuses, and the anterior and posterior ethmoid cells. They are all continuous with the mucous membrane of the nose, covered with a thin layer of mucoperiosteum, have ciliated epithelium, and comparatively few mucous glands. The frontal sinus mucous membrane is said to have none. They are very irregular in shape, practically invisible under normal conditions by rhinoscopic examination, and the diagnosis of their affections presents some difficulty.

The maxillary antrum is the largest cavity, lying in the upper jaw, opening into the nose. On the nasal side it is covered over with portions of the ethmoid bone and the inferior turbinate, and has a small, natural opening into the middle meatus of the nose at about its middle third and very near the highest portion of the nasal wall of the cavity. This opening is 2 to 6 mm. in its vertical, and 3 to 18 mm. in its anteroposterior diameter. Opposite this and behind the natural outlet, there are frequently one or more accessory openings. The outlet of these openings is in the hiatus semilunaris, a crescent-shaped opening formed above by the bulla of the ethmoid, and below by a sharp process called the processus uncinatus. Internal to this, and practically a part of it, is another space called the infundibulum, into which opens the outlet from the frontal sinus, the frontonasal canal. The average size of the antrum is 1¼ inches in its anteroposterior diameter, 1¼ inches vertically, and one inch in width. It is subject, however, to extreme variations in size, and is frequently very different in formation on the two sides of the face. With a high arched palate the antrum is long and narrow. With a sinking in of the canine fossa it becomes much shallower. On its outer wall it is thin and the outer portion of its inferior wall is in close relationship to the roots of the first and second molars and the first and second bicuspids. The roots of these teeth frequently project into the antrum, and indeed the first ideas of antral pathology came from the hands of the dentists, who occasionally found, after removal of teeth, that the antrum contained pus; and our first belief in regard to this subject was that antral suppuration was always of dental origin and the treatment should be by an opening through a tooth root or through the alveolar process.

The floor of the antrum is somewhat irregular. It may be on a level with the floor of the nose. It is frequently lower. The thickness of the bone over the tooth roots varies greatly, being thinnest over the first and second molar teeth. The second bicuspid and the first and second molars have a pretty constant relation to the antrum, the first molar being usually certain as to relation. In entering the antrum, however, in this way, the proper angle of insertion of the tooth must be carefully followed; otherwise in antra of extreme variation from type it is possible to puncture either the floor of the nose or cheek wall instead of the antrum itself.

The maxillary sinus is constantly present. At birth it is a slit with a vertical diameter of 3 mm., transverse of 2 mm., anteroposterior of 7 mm. There is no maxillary sinus beneath the orbit at this time. Later cancellous bone forms between the floor of the orbit and the alveolar process of the jaw, and the antrum is complete at twenty-five years of age, the floor of the orbit being the roof of the antrum. In the roof of the antral cavity lies the infra-orbital canal, transmitting the superior maxillary nerve and the infra-orbital vessels. An occasional defect in this wall may cause pain in connection with antral suppuration. The position of the infra-orbital nerve has especially to be borne in mind in radical operations.

The frontal sinuses are two large cavities in the frontal bone beginning just above the roof of the nose and extending laterally over the roof of the orbit, going half-way up the forehead to the superciliary line and extending about 1¼ inches downwardly. These dimensions vary very greatly, so much so that any average dimension is of little value.

There is always an opening at the most dependent portion down into the nose through what is called the fronto-nasal duct, opening usually into the infundibulum, sometimes in the hiatus semilunaris, occasionally opening directly down into the nose independent of the infundibulum, but always underneath the anterior end of the middle turbinate. The practical import of this is that sec-

1 Presented before the Buffalo Academy of Medicine, March 28, 1904.

ondary infection from antrum suppuration is possible; the frontal sinus on account of the frontonasal canal draining into the hiatus, and also the converse where the drainage of the pus through the hiatus may infect the antrum.

The frontonasal duct varies from a mere slit to one 7 by 8 mm. in size, the average diameter being 4 by 3 mm.

There is almost always a septum between the two sinuses; indeed, Logan Turner says he has never found it absent in the normal skull. Other observers say that it may be absent. There may be a defect of this septum even though the two sinuses do not communicate, the two lining membranes completely closing this defect. In case of empyema of one side there is liability of infection of the other. I have had one such case of bony defect in the septum wall in which one sinus apparently infected the other, though the lining membranes of each sinus were apparently intact. The natural outlet is not visible in the nose on account of the frontonasal duct, the infundibulum and the hiatus being practically covered by the anterior end of the middle turbinate, so that probing and syringing of this cavity is always difficult in the normal nose, and may be impossible until the middle turbinal or its anterior portion is removed. The condition in life with swollen tissues is in marked contrast with the dried specimens, the mucous membrane of which is entirely absent, as it is comparatively easy in the dried specimen to carry a probe into the frontal sinus even with the middle turbinal in position.

The septum of the frontal sinus is usually in a medial plane, but may be to one side or the other, so that it is possible to open the wrong cavity when operating through the anterior wall; but no matter how oblique this division line may be placed above at the lower end and immediately above the root of the nose, the line is usually mesially placed. Occasionally the sinus extends over the entire root of the orbit.

The floor of the frontal sinus is in close relation to the anterior ethmoid cells. The lining membrane of the sinus is slate in color, while the dura, on the other hand, has a white appearance. The outer table is from 3 to 5 mm. thick and if on chiseling, one goes much deeper than that without finding the sinus, he should begin to think either that the sinus is obliterated or that the dura may be the next structure which will be met.

The frontal sinus does not usually appear until about the age of puberty, though signs of development are evident earlier, and develops from two centers of ossification.

The anterior ethmoidal cells vary in number and position from four to six or eight or more, also in size; are in close relation to the roof of the orbit; open, as a rule, into the middle meatus, frontonasal duct, or the infundibulum, but may open directly into the cavity of the nose; are subject to the same inflammatory affections as the other sinuses and are sometimes opened or probed by mistake, the operator thinking he is on the way to the frontal. The posterior ethmoidal cells are fewer in number and open into the superior meatus. These openings are not visible in the living subject, and there is usually a thicker bony division line between the anterior and posterior cells than between the individual cells themselves. Pus in these cavities is quite likely to drain backwards and appear as a sticky mass, more or less dry, on the pharynx wall.

The sphenoidal sinuses, two in number, lie in the body of the sphenoid bone, and vary greatly in size, frequently being very large; have their natural outlet vertically, with their thinnest wall anteriorly, and are reached by following along the septum about the middle of the middle turbinate, and feeling for the same with a probe. A probe passed along this line of the middle turbinal as far as it will reach, the point then depressed to the floor of the nose, would pass directly into the sphenoid cavity.

Here, then, is a complicated spongy network of bone with thin walls all lined with mucous membrane, varying somewhat in the quantity of its mucous glands; subject to inflammatory action, influenced by the swelling of the three turbinal bones which interfere more or less with the natural drainage, and the subject of inflammatory action causing bone pressure, headache and the discharge of mucous and pus.

Given then a pus discharge in the nose, how shall we locate its place? We will see what are the symptoms of inflammation in the individual cavity, and then see if with the picture of the inflammation of each individual place in our mind, we can, in the presence of actual pus, make a sufficiently accurate diagnosis, although it may be said here that an affection of one of these, absolutely independent of that of any other, is comparatively seldom, and it now and then happens that the entire spongy network is simultaneously affected.

ACUTE INFLAMMATIONS OF THE ANTRUM.—The acute type begins with a simple serous inflammation, co-existing with, or the result of, some general inflammatory condition in the turbinates or ethmoid, whereby the natural openings are closed and the outward drainage for a time interfered with. This inflammation later becomes mucous, mucopurulent, or, if it lasts long enough, distinctly purulent.

Influenza, acute exanthemata, operative procedures in the nose, requiring the tamponing of the nasal cavity, head colds, intensified by deflected septa, spurs, enlarged middle turbinates, polypi, or any other local pathological condition interfering with drainage are the principal causes. In spite of the fact that the natural drainage point of the antrum is very much higher than its floor, acute inflammations commonly tend toward recovery, as, owing to the shifting position of the body, especially in sleep, plus the aid of capillarity, drainage is brought about. The blowing of the nose, causing negative air pressure, also favors the removal of the material. The larger the nat-

ural opening, the more rapid the healing. Influenza has been regarded as one of the most frequent causes, yet Fraenkel demonstrated the presence of the influenza bacillus only once in thirty cases. It is probable that in most cases of acute rhinitis there is more or less co-existing inflammation of accessory sinuses which accounts in a measure for the slow healing.

The symptoms are those of pain in the affected side, headache, tenderness on pressure in the canine fossa, a swollen nasal passage with a mucous or mucopurulent discharge. While one-sided as a rule, it is not impossible for both sides to be affected at once. The pain may be that of dull pressure referred to various portions of the affected side of the face and head or sharply located. In cases of dental origin the pain may be referred to the region of the affected tooth. It is my own experience that acute cases of dental origin are comparatively rare. Neither the location of the pain nor its character of necessity definitely locates the trouble. In some cases the pain is very severe and is relieved only by the discharge of mucous or muco pus. Acute inflammations tend to recover and only occasionally become chronic: when they do become chronic it is doubtless due to some interference with the natural drainage.

The treatment consists of general measures directed to the cause, the relief of the pain, douching and syringing with warm salines to favor the discharge, careful examination of the nose, and, whenever possible, the correction of any interference with natural drainage and the hunting for the natural and accessory openings. Washing out through the natural orifice is recommended by many writers, and Curtis says it can be done in three cases out of ten with the Hartmann canula passed ½ cm. from the vestibule. I have not personally been very successful either in finding the natural opening or in washing it out, and have found it much easier and no more painful to puncture underneath the anterior third of the inferior turbinate at the highest point possible, using a curved canula with beveled edge point. This method is quite as rapid and invariably gives one definite information, though one negative puncture is not conclusive evidence that the antrum is not diseased. When the space underneath the inferior turbinate is thoroughly cocainized, with the addition of some adrenalin, the puncture can be made either with the light blow of a hammer or often with the muscular force of the hand, with very little difficulty and practically without pain. The cavity can then be syringed out with warm saline solution, relieving at once the tension and pain and rendering the other measures locally and generally of much more immediate effect.

The ordinary acute case which is seen at the purulent stage will last under this form of treatment from one to two weeks. I am in the habit of syringing out the cavity daily or every other day. A small silver Eustachian catheter easily maintains the opening made by the canula. If it does not, enlarge with a curette. Should the pain disappear and the discharge continue for weeks and be purulent in character, the condition becomes one of chronic empyema. Most cases of chronic inflammation, however, are brought to the physician's attention after they have lasted a long time and arise from two main causes, namely: disease of the teeth, or a primary purulent inflammation of the antrum due to obstructon of the natural outlet, to injuries as traumatism, to the entrance of micro-organisms or to infection from the ethmoid or frontal sinuses. It is probable that the two main causes are about equal in the number of cases which they produce, although some writers lay more to one cause and some more to the other. The varying virulence of the bacteria and the individual predisposition of the individual seem to be the principal factors in deciding whether an acute inflammation heals in the one case or becomes chronic in the other. The form of inflammation is purulent or mucopurulent, sometimes cystic. The micro-organisms found are the *Bacterium coli commune, Bacillus pyogenes fœtidus, Diplococcus lanceolatus,* aspergilli, tubercle bacilli.

The cases of dental origin arise as a result of diseased root processes, especially when the distance between the roots of the teeth and the floor of the antrum is very short. Not infrequently no complaint will be made of the teeth, or it will be reported that they have been filled or have given trouble a long time ago; they may often be apparently sound. Modern dentistry, in its endeavor to save teeth by capping and various methods, not infrequently allows teeth that were better removed to remain in the alveolar process. I have had cases of dental origin which seemed to me to have their cause in capped teeth; others in which no complaint whatever was made of the teeth. In one case an obstinate empyema of the antrum was treated for a long time with daily washings through a tube passed underneath the inferior turbinate. Improvement repeatedly took place, but as soon as the washings were discontinued, the discharge of pus again became foul. No complaint was made of the teeth, but afterward the first bicuspid was extracted, when it was discovered that the alveolar process immediately around the deeper portion of the root was carious. The curette was easily passed into the antrum, all the diseased bone removed, and recovery promptly followed.

The explanation of the lack of symptoms is to be found in the fact that so long as nature has an outlet, she seldom sets up much pain. This is true in those cases of nasal as well as dental origin. Patients will not usually complain of pain but of a unilateral foul discharge. Wherever the teeth are thought to be the cause, the extraction of the teeth and the drilling out of the root cavity will usually determine whether this is or is not the case.

The patients with empyema of the antrum seek

relief either for catarrh, which they say affects one side only, or from the stopping up of the nose and the growth of polypi, due probably to the discharge of pus from the natural outlet (though the polypi may have another cause themselves and be the cause rather than the result of the antral suppuration), or from the constant discharge of foul pus from one side. Obstruction to breathing may be present, with hypertrophy of the mucous membrane of the middle turbinate and of the inferior turbinate. One-sided eczema of the anterior naris is frequent, together with disturbance of the sense of smell, a peculiar odor sense taking its place. This is due to swelling and partial closure of the olfactory fissure.

Diagnosis of Chronic Antrum Suppuration.—As pus appearing in the middle meatus can come from several sources, the question of diagnosis may present some difficulty. On examining the nose with a speculum, white, creamy looking pus will probably be seen in the front of the nose and around the lower border of the middle turbinate. Wipe this away and notice whether it quickly reforms. After it is cleansed thoroughly, lay the head over toward the opposite side, and after a few moments examine again. If pus is still present and underneath the middle portion of the middle turbinate, it is probably of antral origin, as pus from the frontal sinus or ethmoidal cells will be high up or nearer forward, nearer the infundibulum, and rather in front of the middle turbinate. The pus tends to come forward when the individual is in an upright position, while at night it flows into the nasopharynx, and in the morning is found more or less dry on the nasopharyngeal wall. This diagnosis is only presumptive and not absolute. Several examinations may be necessary, as pus may not appear in the nose at the time of the first examination. An absolute diagnosis can be made only by puncture either through the floor of the nose or through the canine fossa, or by the extraction of a tooth. The history of the case will help somewhat in determining whether it is of dental or nasal origin. By lifting the cheek with the retractor or with the finger, and thoroughly cocainizing the mucous membrane of the canine fossa directly over the second bicuspid or first molar, a good-sized canula can easily be driven with a light blow directly into the antrum cavity, or the ordinary dental drill will quickly make an opening. Warm sterile water is then syringed through the cavity, when, if pus appears at the nasal outlet, the diagnosis is positive. A positive diagnosis can also be made by puncturing the nasal wall in the manner to be described.

Transillumination with an electric lamp placed in the mouth has some diagnostic value. In case one antrum is occluded, the shadow on this side will be very much darker and may even be absent altogether. The information which transillumination gives is corroborative only and not of itself absolutely diagnostic on account of the varying thickness of antrum walls and the possible variation between the two sides. It case polypi are present they should be removed as thoroughly as possible. The prognosis must always have an element of doubt about it, inasmuch as if the condition has lasted any length of time, various accessory ethmoid cells may be involved or the frontal sinus. If the entire pus infected area can be removed or gotten into good condition, a cure will result. Where the antrum alone is involved, the prognosis is always good. The odor of the pus is no guide to the prognosis, as long-continued cases may clear up under favorable conditions. The character of the interior of the antrum has more to do with the prognosis than has the question of odor.

Treatment.—In a cavity like the antrum it is necessary, for rapid and complete recovery, to have good drainage. If there is reasonable probability that the purulent condition of the antrum is of dental origin, the offending tooth should be extracted, the opening through the alveolar process enlarged with drill and curette until the cavity can be freely syringed, and the cavity then packed with strips of gauze and syringed daily until recovery takes place. If the pus still continues after a reasonable length of time, it is evidence that the cavity of the antrum is itself involved in the diseased process and in that case it is better to do the radical operation about to be described.

In making the preliminary puncture under the anterior end of the inferior turbinate, whether for diagnosis or for treatment, some details are to be borne in mind. The point of puncture should be just behind the anterior portion of the middle third of the inferior turbinate. Cocainize thoroughly with 20 per cent. cocaine and adrenal solution, carry the point of the trocar to the proper place, and as high up as possible underneath the turbinate, and not on the floor of the nose, where the antral wall is much thicker. Either a straight or a curved canula with a trocar or a sharp beveled edge canula, straight or curved, without trocar, can be used. After finding the point for puncture, carry the canula against the outer edge of the septum so as to pierce the antral wall at as nearly right angles as possible. Hold it firmly with the fingers of the left hand, and tap lightly on its end with the mallet. After one or two light taps with the mallet, it will be felt to enter the antrum, the giving way of the sense of resistance being evident to both fingers and mallet. Move it about a little to be sure that it is in a free cavity. In some narrow antra, if puncture is made too far forward, the canula can be carried into the cheek. This is more likely to occur where the canine fossa is very much depressed. I have had this happen once and blew some air into the cheek. The experience, while devoid of danger, was an unpleasant one. In this instance puncture was made too far forward, as a subsequent puncture, the canula being inserted a little further back, discovered the presence of pus. An absolutely sterile trocar and canula is to be used,

and if no pus is present, no harm will be done. If a canula without trocar is used, be sure that it is permeable before introduction. As soon as the canula is in position, sterile water is syringed through it, when pus, if present appears in the middle meatus. If none is found, and it is an acute case, a few washings through the canula may effect a cure; hence it is desirable to leave the canula in situ, or what I regard as better, to enlarge the opening with drill or curette so that a curved canula can be easily introduced for a short time at least. The ordinary non-bulbous silver or hard rubber Eustachian catheter answers very well as a canula for daily introduction. This enlargement of the opening is usually not difficult to make, provided the area has been thoroughly anesthetized. By still further enlarging this opening under the inferior turbinate with a nasal cutting forceps of the alligator type, I have been enabled to get and maintain a good-sized opening, through which washing can be done by the patient without difficulty, and have obtained cures in cases where I had supposed a radical operation would be needed.

In all cases in which the pus has lasted for any length of time and is foul, and resists temporary treatment, more radical measures will be needed. Any obstruction to drainage in the interior of the nose should first be removed, preferably under cocaine anesthesia, and some days previously. The patient is then etherized. (If there is any suspicion of the case being dental in origin, the suspected tooth is removed and a good-sized curette passed up into the antrum cavity, through the alveolar process, the instrument being directed backward rather than absolutely vertically. The ordinary dental drill is not usually long enough or large enough. This was formerly the only method of treatment, but has many disadvantages, owing to the constant tendency of the alveolar process to close, and the consequent difficulty of maintaining an opening for a sufficient length of time to be sure that the drainage is complete and long continued enough to bring about a cure in the antrum.) A horizontal incision, one inch long, is made where the mucous membrane folds on to the cheek and at the point between the second bicuspid and first molar. The periosteum is laid bare above and below, and the edges of the wound held back with elevators; a small opening is made with the chisel, and this enlarged with chisel or cutting forceps so as to give an opening sufficiently large to put the finger into, and allow room for thorough inspection. The bleeding will be profuse at first, but is easily stopped by pressure. The mucous membrane is then inspected, and the treatment carried on according to its condition. If simply purulent it is thoroughly cleansed, curetted a little if need be, but not entirely removed unless extensively diseased, and packed with iodoform gauze. Soaking the gauze in adrenalin solution 1-10,000 will lessen the hemorrhage of the operation. In case there is granulation and extensive disease, the whole antrum area is thoroughly curetted of its mucous membrane, the natural opening into the nose either enlarged or else a new one made underneath the inferior turbinate sufficiently large so that it will never completely close, the cavity packed with iodoform gauze, and the flaps allowed to come together into place. No suturing is necessary, as long before the cavity is completely healed the mucous membrane will have united and nature will have formed what is practically new bone on the periosteum.

The after-treatment consists in daily washing with diluted antiseptic solutions, as hot boric acid solution, Seiler's solution and the like. The gauze is kept in until suppuration seems to have ceased and healthy granulation has begun to form. The opening must be maintained some time after apparent cure, as otherwise the condition may recur. The difficulty in operations of this class is not that the opening remains open but that it closes too soon. In all of my cases the bony opening even when made very large has rapidly closed. No deformity or falling in of the cheek follows this operation.

Some authors close up the opening through the canine fossa by stitching the edges of the wound together at the time of operation, and complete the after-treatment entirely through the nose. This obviates the disagreeable taste of iodoform or any other gauze, but to me has had the disadvantage that it did not allow sufficiently long inspection of the cavity. By maintaining the opening through the canine fossa for a few days, one is able to inspect the entire antrum cavity with light and see whether any shreds or bits of tissue which ought to have been removed at the primary operation still remain. If that is the case, they can be removed. Inasmuch as the edges of this wound usually unite without difficulty, and should they fail to do so, a little freshening of the edges will readily unite them, it has seemed to me an advantage to maintain this opening for a certain length of time.

The after-treatment is comparatively simple. Complete cure will usually take place though the length of time may be considerable. I have seen cases of the foulest antrum disease of probable dental origin heal with entire cessation of discharge in from three to four weeks after the opening into the canine fossa and the alveolar process. Cases of purely nasal origin are usually entirely healed in a few weeks, and if the opening into the floor of the nose is maintained for permanent drainage, there is little liability of recurrence.

A complete operation with good drainage, while it may appear more formidable and radical at the time it is done, is much more satisfactory both to operator and patient, since the time of healing is shorter and the disagreeableness of the after-treatment much less.

In cases complicated with frontal sinus disease it will occasionally, though rarely, happen that an opening may have to be kept through the canine fossa for some time. I have had one case in which a small opening was maintained for nearly two years, healing of the empyemata of both cavities finally taking place.

Acute Inflammation of the Frontal Sinus.—These occur in connection with the ordinary acute inflammations of the nasal membrane, such as acute colds in the head, grippe and the exanthemata. They are due to the extension of the inflammation along the mucous membrane, or to obstruction of the natural outlet.

The symptoms are headache, a sense of constriction in the forehead, pain over the sinuses and at the inner angle of the eye and region of the supra-orbital notch, accompanied by secretion. The secretion consists of mucus, mucopus, or it may be purulent, although acute purulent inflammation of the frontal sinus is comparatively rare. The sinus may also be acutely inflamed as a result of disease processes in the neighborhood of the middle turbinate and ethmoidal cells, which processes interfere with the natural drainage from the sinus.

Diagnosis.—This is made from the symptoms in case there is no discharge of any amount other than mucus or mucopus. If pus itself is present, it may be seen on looking into the nose, at the anterior end of the middle turbinate and quite high up. It is not always possible to differentiate inflammation of the frontal sinus from acute purulent inflammation of the antrum or acute purulent ethmoiditis, although the fact that the pus discharge is not influenced by position, is constant in amount, appearing after being wiped away, will lead to the suspicion of its coming from the frontal sinus.

Treatment.—The acute inflammation usually takes care of itself with the subsidence of the cause. Internal remedies which reduce inflammation, sprays, and frequent syringing with warm or hot saline solution, produce the best results. In case the inflammation is purulent, the removal of the anterior end of the middle turbinate and the clearing of the neighborhood of all possible obstructions will very likely bring about a cure by itself, inasmuch as the natural drainage of the cavity is downward.

Many obscure cases of headache labeled frontal neuralgia of one sort and another are due to interference with the normal ventilation of the frontal sinus. Pain may also co-exist with a certain amount of mucopurulent discharge from the sinus, the quantity of which is so small that inspection reveals no pus. Two recent cases illustrate this, both of which improved after removal of the middle turbinate.

The first was that of a physician who suffered intense headache with inability to do his work. He was taking large doses of codeia with only partial relief. Examination showed a swollen middle turbinate, the removal of which caused some relief. Following this removal it was possible a day or so later to pass a canula clear into the frontal sinus, and a considerable quantity of mucopus was washed out, after which recovery was prompt and complete.

The second case was that of a man complaining of intense pain in the region of the right eye, for which he was sure his eyes were at fault, but repeated visits to the oculist had given no relief. Examination showed a swollen middle turbinate which was promptly removed; a frontal sinus canula was then introduced, and some mucopus syringed out, with immediate subsidence of all the symptoms and no further complaint of the eyes or of headache.

Chronic Inflammation of the Frontal Sinus.—This condition is usually due to long-continued inflammatory processes in connection with ethmoiditis, polyp formation, inflammation of the antrum, or to any cause that has interfered with the natural drainage of the frontal sinus and been productive of more or less inflammation in consequence.

Symptoms.—These are a chronic discharge of more or less foul usually thick pus, accompanied by more or less pain, headache and general discomfort in the region of the sinus. Pain on external pressure may or may not be present. It is usually best elicited when pressure is made at the inner angle of the roof of the orbit, *i.e.*, on the floor of the sinus. There may be obstruction to nasal breathing owing to polyp formation or to the frequently accompanying ethmoiditis.

Diagnosis.—The diagnosis is made by inspection of the site of the nasal discharge in connection with the general symptoms. The diagnosis may be difficult, especially when polyp formation or swelling of all the adjacent mucous membrane is an accompanying feature, as it frequently is. In this case the polypi must be removed and the source of the pus explored until we are certain of its point of origin. With the probe curved in accordance with the natural course of the canal it is sometimes possible to pass it directly into the frontal sinus. While this procedure will in many cases fail, it should always be tried. Thorough cocainization and the use of suprarenal solution will help to shrink the tissues and materially aid the procedure. The diagnosis will be helped by the removal of the anterior portion of the middle turbinate. In all cases where there is even suspected trouble with the frontal sinus or where there seems a crowding together of the middle turbinal against the septum, it had better be removed. I have several times removed it for pressure symptoms either in connection with the eye or for difficult breathing, and have never regretted so doing. It at times enlarges so that it interferes materially with respiration, and whenever acute colds or congestion takes place, occupies so much room as to produce pain. The best method of removal is the following: Cocainize thoroughly, and then

blanch the tissue with 1-1,000 adrenalin. With small-sized alligator forceps make a cut at the highest part of the middle turbinate as deeply as possible. Make a counter cut on the lower border as far back as it is desired to remove the bone. Place the wire of a stout snare in the spaces made by these two cuts, and slowly tighten. The anterior half of the middle turbinate will then come away as one piece. Any portions remaining are easily removed with cutting forceps. On account of the liability of hemorrhage it is safer to pack lightly for twenty-four hours with gauze or cotton saturated in peroxide of hydrogen and oil, equal parts. The addition of the oil renders the removal of the pledget easier and is itself of some hemostatic value. The passage of a probe up into the sinus may be impossible before this is done, and quite possible afterward, owing to the additional room provided.

After the passage of the probe, an attempt should be made to introduce a canula, bent according to the shape of the probe, up into the sinus. Water can then be syringed directly into the sinus or air blown in, and the appearance of pus at the nasal end of the canal, or the presence of a foul odor, will render the diagnosis certain. The sensations of the patient will be of material aid in determining whether the canula or probe is really in the sinus; since it is very easy to pass the instrument into some of the anterior ethmoidal cells and imagine it to be in the sinus. I have found the sensations of the patient, as to whether the syringed fluid or air were really in the sinus, quite reliable in the main, though of course sometimes misleading.

Treatment.—Given a diagnosis, what is to be done? This will depend on various circumstances, such as the age of the patient, the long standing of the disease, and the desire of the patient for a radical cure. There are two methods of operation—the internal or nasal, and the external.

The Internal Operation.—This consists in the endeavor to cure the disease through the nose by the establishment of direct gravity drainage as complete as possible, in the way indicated under diagnosis. Remove the middle turbinate and all obstacles to drainage that can be removed, and then carry a canula up into the sinus as far as possible and syringe daily with a cleansing solution. I have found 1-8,000 or 1-10,000 corrosive sublimate, 50 per cent. enzymol or alkalol to be most efficient. The corrosive should be followed by an alkaline douche through the nasal cavities and pharynx, to offset its irritant effect upon the tissues. Sometimes a cure seems to be effected in this way, or else the discharge diminishes very materially, and the disease ceasing to be a source of discomfort to the patient, he passes out of observation, satisfied with a condition in which the odor has ceased and the headache and pain are no longer troublesome. In many persons one has to be content with this method of treatment, which always results in improvement, though not always in an absolute cure.

The External Operation.—When an absolute cure is desired, or when there are symptoms of pressure, continued headache, pus absorption with increase of temperature and symptoms indicating inefficient drainage, external operation should be considered and advised. Although, if the bone destruction is considerable and the ethmoid cells are extensively diseased, as they may be, an absolute cure may fail or be attained only after a long time, nevertheless, in the majority of cases the cure will be complete, there is no appreciable external deformity, the operation is practically devoid of risk, and the period of after-treatment is not extremely long.

Method.—There are a number of external operations, but I shall describe only one, since that one is generally feasible (though not as radical as the recently described operation of Killian) and has, to my mind, more to recommend it than any other.

The diagnosis being sure, the eyebrow of the affected eye is shaved and the skin rendered aseptic. As the bleeding is considerable from this operation, it is a good plan to place a tampon in the nasopharynx at the time of the operation, so that all the blood will pass out through the front of the nose. A curved incision is then made from just inside the supra-orbital notch along the lower third of the eyebrow region and as far as or a little below the root of the nose. The periosteum is laid bare and the edges of the wound held back by retractors. With a small chisel an opening is now made at about the middle of the incision in the direction of the sinus, and continued until the sinus is reached. The operator will occasionally be surprised at the depth he will have to chisel before reaching the sinus, as the wall is comparatively thick at this point. As soon as an opening is found, it should be explored with the probe so as to be sure which sinus has been opened since the division line is not always in the middle. If the bone be opened immediately above the root of the nose in the angle between the inner third of the supra-orbital margin and the mesial plane of the forehead, a sinus, if present, will always be opened up. The presence or absence of pus and granulation tissue and the character of the mucous lining are next determined. This being accomplished, the opening is enlarged sufficiently to render all parts accessible to the probe or curette, and the sinus curetted or not in accordance with its condition. If extensively degenerated it should be vigorously curetted and all its ramifications followed up; otherwise considerable diseased tissue will be left behind. Hunt especially for pockets. As soon as this is done, the natural opening into the nose through the frontonasal canal should be explored with the probe and then enlarged with the curette, so as to make the largest opening possible without injury to any other struc-

tures. If the opening with the curette is made outwards and backwards there is little danger of doing any damage, and at the same time the adjacent anterior ethmoidial cells, which are almost always affected, can be reached and opened. As this opening is essential to drainage, and gravity drainage favors rapid healing, it should be made as large as possible, and all cells broken down. The little finger in the nose will be a guide to the direction of both probe and curette. To maintain the opening down into the nose, a good sized rubber drainage tube is next inserted, one end appearing at the nasal entrance and the other at the sinus end of the external wound. This should be maintained for a week or ten days so as to keep the opening into the nose a sufficient length of time during the process of healing. The question of the closing of the external wound must next be decided. If one could be sure that all the diseased tissue had been removed and the process had not existed too long, and there was little or no bone destruction, the external wound might be closed. There is, however, some danger of recurrence from re-infection from the nose, and as a result of several years' experience, I now favor the maintainance of the external opening and the complete obliteration of the sinus cavities, as in some of my former cases in which I allowed the wound to close after a period of even one or two weeks, I was obliged to re-open. In one instance there was no recurrence for three years, when, during an attack of grippe, the sinus became re-infected. A large opening was then made with thorough removal of all softened bone, and the case treated by the method of obliteration. This requires a much longer time in the after-treatment, from two to four or five months being necessary according to the rapidity of healing and the size of the sinus. It is packed every other day with gauze tampons, especial care being taken to maintain the external opening. When healing has finally taken place, both sinuses are firmly filled and the external deformity is practically nil. Should there be extensive ethmoiditis, the length of time for healing will be materially lengthened. Here it is better at the time of operation to destroy every cell which can possibly be reached. Although apparent healing is obtained in much shorter time by closure of the wound and the reliance on nasal drainage, and although I have had several apparently satisfactory cures by this method, yet the number of recurrences has been considerable, so that I most empathically recommend the endeavor to obliterate the sinus cavity.

Where the sinus is very, very large, it has been recommended to do the operation above the supra-orbital ridge. Take away the entire front wall of the sinus to allow the soft parts to sink in, doing immediate closure except at one angle of the wound, and filling any deformity which may remain by the injection of paraffin. Here the amount of deformity is much less than would be expected, as the subcutaneous tissue seems to expand to a certain degree so that the sinking in is comparatively small.

A much more radical operation, that of Killian, has recently been recommended in which the entire removal of the floor of the sinus and all its anterior wall, with the exception of a slight bridge corresponding to the supra-orbital ridge, with immediate closure of the wound, is recommended. This operation is very extensive, gives rise to considerable deformity, and has, as yet, not received any great favor in this country, although as now perfected by its author, it is said to be free from the danger of recurrences, and to have less deformity than would be expected.

Sphenoid sinus disease was formerly thought to be comparatively rare as a primary condition, but recent investigations have shown that the sphenoid is invaded by purulent processes more frequently than was formerly supposed. In many subjects it can be probed and examined with comparative readiness. In others, the removal of a portion of the middle turbinate is necessary. When pus is present, the anterior wall will have to be removed in order to maintain drainage, as the natural opening is at the most superior part of the sphenoid cavity.

The *anterior ethmoidal cells* as such may be primarily involved and the condition of purulent ethmoiditis be present. This will usually be accompanied by formation of polypi, bare bone, and other evidences of disease of the walls of the individual cells. Remove with a snare and curette all the polyps which are present, break down as many of the individual cells as possible under good illumination, and clear them out. Repeated operations of this type will probably in time so far clear up the case as to render the patient's condition practically normal, although it must be conceded that many times there still remains more or less purulent discharge. As, however, the condition of these cases is invariably helped, the patient's condition is so much better than his former one that the occasional discharge of a little pus from the nose ceases to be an annoyance to him.

So much then for a rapid résumé of the individual affections. In many instances one has to do not with the simple empyema of one cavity but an empyema of one or more cavities, due to the fact that they easily infect one another. The frontal sinus not infrequently infects the antrum and, indeed, in those cases in which the sinus seems to be the only cavity diseased, it has seemed to me, as a result of experience, that it is always safer to open and provide for the time being a drain from the antrum, inasmuch as during the healing of the frontal sinus inflammation, sufficient pus may drain into the antrum from the infundibulum or hiatus to infect that, and a secondary antrum inflammation be produced at the same time that the cure of the frontal sinus inflammation is taking place.

Briefly to sum up, the patient presents himself to us with pus coming from one or both sides of the nose. What is the plan of procedure?

1. Clear the nose of all visible sources of obstruction, especially polypi, which easily grow or are maintained wherever and whenever surfaces are bathed with pus.

2. Examine the teeth to see whether there is anything in the way of probable dental origin of sinus trouble.

3. With the nose carefully cleaned, endeavor to ascertain, if possible, by inspection whether the pus seems to come from the antrum or from the frontal sinus or from various points in the ethmoid cells.

4. If the apparatus for the same is at hand, try transillumination, not only for the antrum but also for the frontal sinus as well.

5. Make an exploratory puncture of the antrum in the manner I have already described.

6. If the antrum is free, explore the frontal sinus for the pus, try to wash out with the canula, or to pass a probe, if possible. If not, next remove the middle turbinate. If the antrum contains pus, endeavor to cure it by washing out for a reasonable length of time. Failing in that, do a radical operation. Remember that the better the drainage, the faster the cure, and do not content yourself with a small pin-hole opening made by a small dental drill through a root cavity.

7. If the pus appears to come from the frontal, wash it out with a canula if possible, pursuing this treament a reasonable length of time, and being guided as to the question of a future operation somewhat by the feelings of the patient; somewhat by the annoyance of the discharge; somewhat by the chronicity of the case, remembering that the frontal sinus is a simple, large, irregular cavity, that it may communicate with one or more of the anterior ethmoidal cells and that the operation, while not of itself especially serious, may mean a long and more or less prolonged course of after-treatment. Do not fail to do it or have someone else do it in case it seems indicated.

8. Where there are several empyemata it is better to clear out the nose as thoroughly as possible and then, under ether, do the operation on all the cavities at once.

Careful study of the individual case over a sufficient length of time will usually bring one finally to success and the results are worth all the time and effort spent upon them. So far as the general practitioner is concerned, it seems to me that when it comes to the operations, they had best be done by someone skilled in that line, although it is essential that the general practitioner to whom the patient in all probability originally comes, should know sufficient about the case intelligently to advise his patient and should at least have a good mental picture of the pathological processes going on.

When more attention is paid by the average practitioner to the real pathological conditions present in the nose, and they are not all dismissed under the heading of catarrh or neuralgia, progress will have been made.

Note.—In the preparation of the foregoing the author has drawn somewhat from the chapters covering the same subject in his book, "Nose and Throat Work for the General Practitioner."

MEDICAL PROGRESS.

MEDICINE.

Excretion of Purin Bases in Feces.—According to A. Schittenhelm (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 5 and 6), the normal feces of man always contain purin bodies, but the amount is small and very variable. There seems to be a direct relation to the amount of dry residue: If this is large, the amount of purin bodies is also relatively high. They are also present in the feces after an absolute carbohydrate diet, since the intestinal contents will here contain more bacteria and a more active desquamation of epithelial cells will take place from the intestinal walls. Food rich in nuclein, such as thymus, will also increase the amount of purin, but the bases normally present in muscle seem to be well absorbed. There is generally a decided increase with diarrhea, a diminution in constipation, since absorption is increased, and since the prolonged action of bacteria will convert amniopurin into oxypurin, which passes more readily through the intestinal walls. A diminution is also common with pancreatic disease and in alcoholic stools. Uric acid is generally found in meconium, but never in the feces of extra-uterine life. The purin bases in the feces are chiefly present in a free state, but a small percentage is combined with nuclein and another portion with pentose and hexose. Purin bases occur regularly in pancreatic secretion, but never in bile unless the biliary passages are inflamed. Adenin and guanin are abundant in the walls of the intestines, together with smaller amounts of xanthin and hypoxanthin. Probably a large percentage of the purin bases in the feces is derived from this source.

Absorption of Potassium Iodide from the Stomach.—More than twenty years ago a new method was introduced, to determine the degree of absorption which goes on from the stomach in health and disease. The patient received a capsule containing potassium iodide, and the saliva and urine were then tested at stated intervals for this salt. The value of this method has been frequently doubted, so that the experiments of K. H. Baas (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 5 and 6) are of the greatest practical importance. This author discovered that a moderate dose of morphine caused a spasm of the pylorus, so that nothing can leave the stomach by way of the pylorus while the effect lasts. The urine of dogs and rabbits which received a dose of morphine before the iodide was administered, gave a very late iodine reaction, while without morphine the test was positive in a few minutes. In man, a closure of the pylorus also takes place after morphine, and there can be no doubt that iodide of potassium is not at all absorbed from the stomach, and hence unfit for testing the motility.

Notes on Diabetes.—From the careful analysis of of a severe case of diabetes, A. R. Mandel and G. Lusk (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 5

and 6), conclude that the relation of dextrose to nitrogen in urine is of great prognostic value. In absolute diabetes, such as results from the injection of phlorhizin into animals, the preparation is generally 3.65 to 1; it follows, if the same figures are obtained in human beings, after a simple fat-meat diet, that the intolerance for sugar is complete and the prognosis very bad. With less excretion of sugar in proportion to the nitrogen, a certain amount of improvement is always possible. The presence of acetone, diacetic and oxybutyric acids in the urine need not always be alarming, for patients have been known to excrete 5 to 6 grams of acetone and 30 to 40 grams of oxybutyric acid, and still improve considerably. There is no reason to believe that the ingested fat participates in the formation of sugar, even if figures higher than 3.65:1 are obtained; it is more likely that the excess of sugar is derived from proteid taken the day before, since the nitrogen of proteids is always excreted more rapidly. Yeast had no influence whatever on the amount of sugar. When the patient was fed on oatmeal and levulose, 85 per cent. of the starch of the former and 80 per cent. of the latter appeared in the urine as sugar. Recently Clowes has constructed a formula for determining the percentage of sugar in urine, if the specific gravity and freezing-point are known, but the authors have found errors up to 1.5 per cent., which make this method incorrect. It is a strange fact that in dogs with extirpated pancreas, the D:N ration never exceeds 2.8:1; this is best explained by assuming that after phlorhizin, the kidneys are able to decompose a compound of proteid and dextrose which is normally burnt up in animals which show the proportion 2.8:1.

Ascaris in Biliary Passages.—It is well-known that the *Ascaris* possesses the property of forcing its way through narrow openings to a high degree, and it is believed by many that the worm can get into the biliary passages and give rise to symptoms of gallstone colic and sepsis. That this is indeed possible is demonstrated by a patient of EBSTEIN (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 5 and 6). This patient suffered from all the symptoms of obstructive jaundice and biliary infection until she passed several worms, one of which clearly showed a deep constriction near its head, proving that it had lodged in a narrow canal. The patient recovered completely and had no recurrence for eight years.

Relation of Articular Rheumatism to Angina.—The type of angina, which most frequently precedes an attack of acute articular rheumatism is the chronic desquamative type of tonsillitis, according to D. GÜRICH (*Münch. med. Woch.*, November 22, 1904). That there must be an intimate relation between the two conditions is proven by the following: Several patients suffering from recurrent rheumatism were treated with the salicyates, with excellent, but only temporary relief. It then occurred to the author to curette out the tonsillar recesses and ever since the operation, the patients, have remained free from rheumatism. The symptoms of the tonsillar affection are neuralgia, fetor from the mouth apparently without cause, and often globus hystericus. It is often difficult to see the crypts with their stagnating contents, since they are lodged in the fossa behind the tonsil proper.

Etiology of Facial Paralysis.—Undoubtedly exposure to cold is the most common cause of facial paralysis. D. STENGER (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 5 and 6) does not, however, believe that the nerve is easily affected by cold at its most exposed portion, the stylomastoid foramen, but thinks it is particularly vulnerable in its course within the tympanic cavity where it often lacks its bony covering. The sudden change of temperature is followed by an exudation into the nerve-sheath which results in paralysis owing to the pressure it exerts upon the nerve. If a rhinoscopic examination be made in cases suffering from facial paralysis, the side and the Eustachian tubes should be open, so that a cold draught of air can easily reach the tympanic cavity and hence the facial nerve.

Congenital Icterus with Splenic Tumor.—A most peculiar pathological condition came under the observation of H. V. KRANNHALS (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 5 and 6). A patient presented himself for jaundice and its concomitant symptoms, which had troubled him since early childhood. Otherwise he felt perfectly well, and physical examination was negative, except for a fairly large, firm spleen. Further questioning elicited the remarkable fact that several sisters and brothers, his mother, grandmother and aunt, and some other more distant relatives were just as yellow and also complained of an abdominal tumor. The urine of the patient contained no pathological elements except bile; his feces were never acholic and his blood showed a moderate anemia with polychromatophilia. The pathology of the condition is not known since autopsy records are not at hand, but it is likely that the enlargement of the spleen is the primary condition, and that the bile in the serum results from the action of some toxin on the liver.

The Copper Treatment of Water.—This new method of antisepsis has been investigated by HENRY KRAEMER (*American Journal of Pharmacy*, December, 1904). For testing copper sulphate two aqueous solutions of strengths 1 in 100,000 and 1 in 1,000,000 were employed, of the total number of organisms exposed there was a reduction of 99 per cent. with the stronger solution and of 90 per cent. with the weaker. For testing colloidal copper, strips of copper foil were used, and 85 to 97 per cent. of all organisms were destroyed. Special tests were made of the colon and typhoid bacilli, using pure cultures developed in bouillon from eighteen to twenty-four hours. Two 3-millimeter loops of each were added to 200 c.c. of each of the following: (1) Ordinary tap water; (2) tap water which was filtered; (3) filtered tap water, which, after treatment with potassium permanganate, was distilled three times in apparatus constructed entirely of glass. All the solutions had been sterilized at 110° C., for thirty minutes. After adding the cultures a portion of each solution was separated for control, and copper foil added to the rest. They were kept at 35° to 37° C., and plates were made at the time of the culture, and after four, eight, twenty-four and forty-eight hours. The plates were kept at constant temperature for two days in the case of *Bacillus coli*, and for five days in the case of *Bacillus typhosus*. There were no organisms of either kind on any of the plates taken after exposure to the copper, even after only four hours, though the plates taken at the time of adding the culture showed from 4,410 to 11,246 of *Bacillus coli*, and 1,400 to 3,986 of *Bacillus typhosus*. Plates from the controls showed from one to two million *Bacillus coli* at the end of forty-eight hours; in the *Bacillus typhosus* controls there were practically the same number of organisms whenever the cultures were made during the forty-eight hours. It may be concluded, then, that the colon and typhoid bacillus are completely destroyed by placing

clean copper foil in the water containing them. By adding copper foil about 3½ inches square per quart and allowing to stand over night, any householder can purify water.

Scarlatiniform Rashes.—The primary rash of scarlet fever, as observed by A. D. HEATH (*Birmingh. Med. Rev.*, October, 1904), is bright brick-red, appears first on chest, neck and upper arms, spreads downward, and is fully developed in about two days. It has generally completely disappeared in a week. The rest of the condition is made up of closely-set minute red papules surrounded by erythema. The face is flushed, the region around the mouth quite pale, and the typical punctiform eruption skips the face except sometimes the forehead and temples. Over the flushed surface of the face a fine powdery desquamation, like the bloom of a peach, soon develops. Desquamation, usually well marked at the end of a week, begins on the face, neck and chest, and lasts a long time.

The eruption of German measles appears first on the face as scattered pinkish-red spots, darker at the center than at the periphery. It spreads rapidly and may reach the feet in twenty-four hours. On the trunk and limbs the spots may coalesce and may resemble the rash of scarlet fever. There may be no desquamation, or it may be furfuraceous, and usually lasts only two or three days. In measles the rash appears, first, on the temples, at the hair margin of the forehead, behind the ears, and at the upper part of the neck. The spots are distinctly papular, may become purplish, may be crescentic in shape, and may occur in groups. The eruption spreads downward and reaches its maximum on the third day. The face is flushed and spotted, and the region about the mouth may be thickly covered with papules. There is a condition, generally met with in summer, in which a roseola appears suddenly on neck, limbs and trunk without prodromal symptoms or glandular enlargement. Among those erythematous rashes which are classed as skin diseases, are those from friction, heat, cold, certain rays of light, and from various irritants such as turpentine and mustard. Children are very subject to transitory patchy erythema, especially from teething or worms. Enemata may be followed by brilliant scarlatiniform eruptions, more commonly if of soap and water; there may be a great sense of heat in the skin, though the thermometer shows no rise in temperature. Scarlatiniform rashes may also be met with after such drugs as copaiba, antipyrin, belladonna, chloral hydrate or quinine, and in diphtheria, influenza and typhoid fever. The writer has seen extensive rashes following the administration of diphtheria antitoxin, and in uremia, septic conditions, acute rheumatism and tonsillitis. The latter, if on the chest, is particularly difficult to distinguish from scarlet fever. A rarer form of eruption is erythema scarlatiniforme, in which a bright scarlatiniform eruption spreads rapidly over the body, often becoming universal in twenty-four hours. Desquamation begins early, is very free, and may include hair and nails. Frequent relapse is common.

The Protozoan of Scarlet Fever.—An important communication on this subject is published by C. W. DUVAL (*Univ. Penn. Med. Bull.*, November, 1904) on his researches on the "bodies" first described by Mallory in 1903 as being found in the skin of autopsied scarlet fever cases. Their presence in the fresh serum was demonstrated, the inquiry being undertaken on the belief that if these "bodies" lying free in the intercellular lymph spaces represented stages in the life cycle of a protozoan, they could be drawn into the contents of an artificially produced vesicle. In all, 18 cases were studied and the protozoan-like bodies were found in five among those last examined and during the stage of the disease when the eruption was at its height. They were not found in the vesical contents of normal individuals. Furthermore, a careful search of the contents of artificial vesicles produced on chemical injured skin failed to show them. Again, the bodies were not found in the serum from artificial vesicles produced on the skin of other acute exanthemata. In the production of the vesicle aqua ammonia fortior was employed after trials with a number of other agents. The serum in these vesicles is free from leucocytes and red cells.

Laparotomy in Typhoid.—Four cases, with a successful result in all, are reported by FITCH, of the Massachusetts General Hospital (*Boston Med. and Surg. Jour.*, December 8, 1904). Two of these were for perforation. In one of them, the leucocytes showed a fall, contrary to the rule, from 11,000 to 4,200. One was for appendicitis, and one for ruptured pus tube. These were the only typhoids during the year which came to operation, so that the statistics are remarkably good, and very encouraging. In the case of perforation reported in detail, operation was done within four hours, yet the belly contained free intestinal contents.

Treatment of Pneumonia in Adults.—M. MANGES (*Med. Rec.*, December 10, 1904) says that the tendency is to forget that this is a general disease in which there may be great disparity between the local signs and the patient's general condition, severe cases sometimes giving evidence of but slight lung involvement and *vice versa*. So far, the attempts to devise a specific treatment have not been successful, and but little is to be expected in this direction, for the pneumococcus is not always a constant quantity, and various other organisms, including the influenza bacillus, which, of late, has markedly influenced the disease, may be present in mixed infections. The author's detailed discussion of the treatment is subdivided under the following heads: (1) To maintain life. The careful management of the stomach by a suitable diet to prevent distention and the consequent cardiac embarrassment is of the highest importance. It is wiser to give too little food than too much and to avoid all carbonated beverages. (2) To support the heart. The best drugs for this purpose are strychnine, caffeine, alcohol, camphor, and ergot. If prompt results are not obtained all the drugs should be given hypodermatically and in sufficient amount to exert their physiological action. Views as to the value of large doses of digitalis are still divided. Adrenalin, the precordial ice-bag, cupping and venesection are also useful measures. (3) To control hyperpyrexia. Large flat ice-bags on the chest will be found useful, but care is necessary to avoid producing intercostal neuritis. Cold sponging and packs are of value, but must be used with caution, and cold baths are contraindicated. The rational use of coal tar antipyretics in small doses may contribute much to the patient's comfort. (4) To relieve suffering. The cough and pain are combated by the use of small doses of morphine hypodermatically, or of heroin hydrochlorate. The Paquelin cautery is of great value for the pleuritic stitches. Oxygen is probably of less value than is generally supposed. Every effort should be made to secure as much sleep for the patient as possible. (5) To control complications. Pleurisy with effusion, empyema, pericarditis, endocarditis, etc., require the treatment ordinarily pursued.

SATURDAY, DECEMBER 24, 1904.

AN APPEAL FOR AID IN THE FIGHT AGAINST TUBERCULOSIS.

THE appeal recently issued by the National Association for the Study and Prevention of Tuberculosis is a document pregnant with meaning for the future of the country. For years we have watched for the organization of a great national movement, backed by sanitary reformers possessing brains, experience and determination, and commanding the respect of the members of the medical profession who know better than all others the terrible evils resulting from the spread of pulmonary tuberculosis. Here and there local societies have undertaken to grapple with the problem; now and again a municipal or a State health board, wise in its generation, has sent an advance guard against the enemy; but an authoritative national body, ready and able to give sanction to, and by promoting general cooperation, to guarantee the permanent success of local effort was lacking. At last such a body has been formed. The National Association for the Study and Prevention of Tuberculosis, presided over by Trudeau, seconded by Osler, Biggs, Sternberg, Welch, Wyman, Vaughan, Knopf, Flick, and a score more of men of exceptional training and influence, has entered upon a campaign of education and prophylaxis which must not end until the nation is rescued.

The history of tuberculosis does not need to be retold here. That ignorant consumptives are abroad in the land, sowing everywhere without thought or care, the seed of fatal infection, is a truth which is brought home to each one of us by tragical evidence every day. Nor is it necessary here to dwell upon methods for the treatment of tuberculosis, nor to discuss the relative importance of the various agencies by means of which the spread of tuberculosis can be prevented. In the text of the Association, the eradication of tuberculosis is said to be "an issue involving education, sacrifice, patience, improved sanitation and the responsibility of the individual to the cause of public health." The National Association, it is true, is "organized and equipped for a campaign of study and education"; but the ultimate and lasting success of the movement hinges upon the cooperation of cities, States and the nation—not necessarily through existing governmental agencies, but rather through the enlightened leadership of the National Association for the Study and Prevention of Tuberculosis itself. The saving of human life on a gigantic scale is the aim; the National Association is the guide; the local society is the weapon which will prove most effective in the great fight.

We are informed that the National Association will endeavor to effect "the personal and financial cooperation of those laboring to bring about a new conception of the dangers of ignorance," and that "local societies are to be started with the same aims." It is in this connection that we wish to say a word to the Association and to the medical profession. It should be the avowed purpose of the Association to bring about the organization of a society for every locality or district. The consumptive is migratory, and effective education and control will never exist until the country is organized systematically, county by county and State by State, so that there shall not exist within the United States a place where ignorance and the sanitary vices which have their root in ignorance can find a foothold.

To the medical profession we have this to say: The National Association is now properly started under trustworthy auspices. In the formation of local societies the medical profession is bound to occupy the leadership; and it behooves medical men who are sincere, and in the truest sense

patriotic, to protect struggling local associations, on the one hand against indifference, which is almost criminal, and on the other, against the unreal enthusiasm and the hurtful influence of self-advertisement. Local organizations will be transient or permanent, useless or efficient, according to the characters and purpose of their promoters. Not all physicians can hope to be recognized as leaders, either in the national or local bodies, but all can be sincere well-wishers to the movement, tireless workers in the cause of humanity. It rests with the medical profession to teach their fellows what sacrifice and patience are worth in a movement which is destined to find its place in history among the greatest efforts for the preservation of the race.

THE ROLE OF THE OXIDASES IN THE ANIMAL ECONOMY.

"Life is a series of oxidations," has become an important formula of modern physiology. The manifestation of heat and visible motion, in which respects alone life reveals itself to physicist and chemist, has been amply explained in the basis of an oxidation of the complex organic compounds out of which the tissues are built.

Not content, however, with this conclusion, physiologists have probed more deeply into the mechanism of vital oxidations, and discovered that these processes are brought about by certain unorganized ferments present in the tissues, and called oxidases. The discovery of these substances has opened up a glittering world of possibilities to the investigator.

The oxidases are catalytic agents possessing the property of uniting with molecular oxygen and delivering it in its atomic or active form to the tissues. These enzymes are present in all parts of the body and have been discovered even in the milk and urine. They have not been isolated in their pure state, but their presence has been definitely demonstrated by a variety of well-known tests.

The practical importance of investigation on the nature of the oxidases and their mode of operation can not be overestimated. It was not entirely poetic imagination that inspired Jacques Loeb to predict that through the oxidases one may in time be able to control life as the artist governs the keys of the piano. Not merely the normal course of life, but also that vast gamut of diseases characterized by metabolic derangements, might be controlled if we only knew how to favor or retard the action of the oxidases.

Recent researches in this domain, valuable in themselves, are still more valuable as an earnest of the rich harvest which the future holds. L. Liebermann has pointed out a close analogy between colloidal platinum and the oxidases. The former, which has for a long time been known to act as a catalytic agent in the decomposition of peroxide of hydrogen, owes this power to the active oxygen which it contains. The colloidal solutions of platinum possess the capacity of activating molecular oxygen. In this process loose compounds of platinum and oxygen are formed. The catalytic power of colloidal platinum is increased by the passage through it of some inert gas, such as hydrogen or nitrogen, which action is attributed to the mechanical agitation produced by the streaming gas which by breaking up large particles of the platinum, renders this capable of uniting with a large amount of oxygen. The surface attraction of the large extent of surface represented in the very fine particles present in solution, is capable of tearing asunder the constituents of the inactive oxygen molecule.

It is highly probable that the oxidases act in a similar manner. If this is really the case, then physical phenomena would play a large part in either retarding or accelerating the action of the oxidases. May not the supposed beneficial effects which follow vibratile stimulation of the organism be possibly connected with some mechanical influence on the oxidases? May not the normal rhythmic beat of the heart and muscular exercise favor the metabolic processes of the body by acting in a mechanical way upon the oxidases?

In this connection the recent experiments of A. Lowy and F. Müller are of interest. In studying the influence of sea-climate and sea-bathing upon metabolism, these investigators found that the latter is increased by west winds and an increased force of the waves, which act as physical stimuli.

The experiments of L. Liebermann on colloidal platinum also open up a vast field of possibility in the domain of pathology. This observer states that the mechanism of the oxidative reaction helps to explain certain phenomena connected with the destruction of foreign and toxic bodies in the organism. Certain pathogenic bacteria are rendered innocuous by uniting with protective bodies normally present in the organism, the complements of Ehrlich. But these act so slowly that they cannot fortify the organism against an intoxication. On this account another body is

necessary, the amboceptor (immune body), which will unfold the activity of the complement. The analogy to the phenomena of the oxidative reaction is as follows: The pathogenic agent corresponds to the tissue, the complement to the active oxygen, and the amboceptor to the oxidase. The amboceptor is thus nothing more than a catalyzer.

That catalytic agents akin to the oxidases play an eminent rôle in subduing septic processes in the organism is indicated by the recent researches of M. J. Hekman and H. J. Hamburger. These observers sought an experimental demonstration of the clinical experience that colloidal silver has a favorable effect in various forms of bacteria invasion. They found that while solutions of collargolum of a low concentration increase the hemolytic power of staphylotoxin, solutions of a higher concentration entirely inhibit hemolysis. The authors attribute the inhibitory action of colloidal silver to some catalytic effect. In view of Liebermann's experiments on colloidal platinum, this conclusion is probably correct.

SOME MEDICAL JESTING.

The *Münchener medizinische Wochenschrift* issued its usual joke number about a month ago, this time in honor of the celebration of the seventieth anniversary of the Foundation of the Physicians' Union of Munich. Though it has some excellent medical jesting, we are inclined to think that it is not up to its usual standard, and many of the jokes seem heavy and far-fetched.

Several of the articles, however, are excellent, probably the best is that on the physician's wife. A number of very practical bits of advice are given to that wondrous creature from whom so much is expected and to whom, it is said, so much of blessing comes, as the helpmate of the doctor. She is reminded that if she should be in want of certain things in the household, there are a number of instruments to be found in the doctor's office that can well supply many ordinary needs. Amputation saws may be used very effectively for making kindling wood and will even be found of excellent service in sawing joints in the kiethen, if no other means be readily available. She is reminded too that for toilet purposes, if the ordinary hand-mirror be mislaid, the forehead-mirror of the physician, or, better still, for the minute facial toilette the laryngeal mirror of the specialist can be brought into requisition. In case the ordinary chafing dish should fail to work, it can always be remembered that the doctor has an alcohol lamp, and that along side it will usually be found the funnel with filter paper meant originally for a quite different use, but that may well be employed for many household purposes. This last is an especially German touch.

She is told that of course there are many interesting books in the doctor's library and that it is only the proper thing that a doctor's wife should know as much as possible about medicine, and especially about the seamy side of it, and it is suggested that she might well occupy the time during which he is absent on night calls by sitting up for him and making herself familiar with the contents of particular shelves of his library. It is not added that this may give rise to a number of ideas and resultants that are no joke, but then every one must learn by her own experience, though it has been said that wise people sometimes learn by other peoples' experience.

There is an excellent take-off on an especially rare fracture of the wrist which has not yet occured, as illustrated by the Roentgen radiogram which fails utterly, alas! (as they sometimes do) to illustrate. The leading article consists of the romance of a white blood corpuscle, an eosinophile, the red coloration it effects being or seeming to be something of the the same sort of evidence of the feminity of these cells that the presence of a large head of henna-colored red hair would be among human beings. The poor white cell has the usual fate of those in love and finds many obstacles in the path of union with her beloved pyramidal cell whom at first she detested very much. Unfortunately the cataclysm in her affairs is brought about by the occurence of a urethral blenorrhagia in the human being of which she is one of the cell colony and carried away by positive chemotaxis as by another Johnstown flood, she finds death and destruction with many of her sisters as the result of submersion beneath waves of a silver solution in the urethra.

ECHOES AND NEWS.

NEW YORK.

Honors for Dr. Carl Beck.—The Society of Medical Jurisprudence recently elected Dr. Beck its President for 1905. He has also been elected Corresponding Member of the Medical Society of Munich, an honor never before conferred upon an American.

The Eastern Medical Society.—At the annual election of the Eastern Medical Society, held December 9, the following officers were chosen for 1905: Ephraim K. Browd, M.D., President; A. Hymanson, M.D., First Vice-President; Charles Goodman, M.D., Second Vice-President; A. Rovinsky, M.D., Treasurer; M. M.

Stark, M.D., Recording Secretary, and Emil Altmark, M.D., Corresponding Secretary.

Seney Hospital Secures Gift.—The Board of Managers of the Methodist Episcopal Hospital, Seventh Avenue and Seventh Street, Brooklyn, has announced that it has succeeded in raising the fund of $300,000 necessary to secure to the hospital the gift of $125,000 from Mr. and Mrs. William Halls, Jr. The managers will now try to raise a second fund of $200,000. The institution is better known as the Seney Hospital, it having been founded by George I. Seney in 1881.

Dr. Dunning Retires.—Dr. Emily Dunning, who has served for two years as an ambulance surgeon attached to Gouverneur Hospital, received a set of engrossed resolutions from the police and hospital officials with whom she has worked. Miss Dunning has been the only woman ambulance surgeon in the city, having been appointed to the Gouverneur Hospital staff on January 1, 1903. She retired on December 17, and will be married shortly to Dr. Benjamin Stockwell Barringer, former House Physician in a New York hospital.

Vaccination of School Children.—"The Present Status of the Law Relating to the Vaccination of School Children" was the subject of the paper read on December 15, before the conference of sanitary officers of the State, by Deputy Attorney-General Sanford T. Church. After quoting from a decision of Judge Vann in a case involving compulsory vaccination, Mr. Church said: "We may therefore unqualifiedly assert that the statute requiring all children to become vaccinated as a precedent to their attendance upon the public schools of this State is valid and constitutional, and a proper exercise of the police power."

Memorial to Dr. William R. Pryor.—The Medical Board of St. Vincent's Hospital, at the regular quarterly meeting held December 13, 1904, caused the following minute to be entered on its records and sent copies to the bereaved family and to the medical magazines:

"The members of the Medical Board of St. Vincent's Hospital have learned with profound regret of the death of their colleague, Dr. William R. Pryor.

"Of undaunted courage and indomitable perseverance, Dr. Pryor followed truth unflinchingly and the highest ideals without faltering. These qualities, coupled with technical skill of the first order and an unusually acute power and wide range of observation, had won for him an enviable reputation and a commanding eminence in his special field.

"His fine enthusiasm, his frankness and directness of purpose, his readiness to lend a helping hand, were enduring qualites which gained for him the highest prizes of ambition: the gratitude of his patients, the love and respect of his associates. Frederick S. Dennis, M.D., and George D. Stewart, M.D., *Committee.*"

Urgent Needs of Our Hospitals.—That there is real danger of the private hospitals of this city being forced, owing to the lack of funds, to abandon private management and rely for support on the city treasury is set forth by Frank Tucker, Vice-President of the Provident Loan Society, in an article in the last issue of *Charities*. Mr. Tucker says in part: "The critical financial condition in which many of the hospitals of New York under private management find themselves is stated in an emphatic and not to be questioned manner in the thirty-sixth annual report of the Presbyterian Hospital just issued. This hospital, one of the 'big four' in the New York hospital group, has long been noted for its progressive administration, its splendid plant, its famous training school for nurses, and its broad and liberal policy toward the sick without means to pay for medical and surgical treatment. Where is the remedy to be found? The writer again answers the question by urging the raising of a large endowment fund, the income to be used in supplementing the present incomes of the group of New York hospitals which find themselves in the same financial condition as the Presbyterian, the fund to be administered by an independent board of men and women selected for their knowledge of social conditions."

Tuberculosis Directory.—In the Directory of Institutions and Societies Dealing with Tuberculosis, which is about to be issued jointly by the Committee on the Prevention of Tuberculosis of the New York Charity Organization Society and the National Association for the Study and Prevention of Tuberculosis, the attempt is made for the first time to present a bird's-eye view of all the organized work that is being done in the United States and Canada for the care and cure of consumptives and the prevention of consumption.

The Directory is an attractive volume of 270 pages and some sixty illustrations. Part I is by far the most important section of the book, consisting as it does of descriptions and views of the 125 hospitals and sanatoriums in which consumptives may receive treatment, with short introductory articles by Dr. E. L. Trudeau, of the Adirondack Cottage Sanatorium, on "Essential Features in Sanatoriums for Incipient Cases," and by Dr. Lawrence F. Flick, of the Henry Phipps Institute, in Philadelphia, on "Essential Features in Hospitals for Advanced Cases." These introductory articles supply a standard by which the average reader can judge of the value of existing institutions in many points and they furnish suggestions to persons who are planning new ones. The descriptive list of existing institutions will be a welcome guide to the physicians and friends of consumptives, whether poor or well-to-do. The exact name and location of each hospital and sanatorium is given, and charges and other terms of admission, the number of patients received, directions in regard to applying for admission, a more or less extended description of the situation, and in many instances views of the buildings or grounds. They are arranged according to the states in which they are located, and are in this way very easy to refer to. An index further facilitates reference by classifying them according to the prices charged and according to the stage of the disease for which they are intended. The section on dispensaries is particularly interesting to charitable workers and physicians who have a large practice among the poor, for it gives the location, office hours, and other details in regard to the thirty-two special dispensaries for the free treatment of tuberculosis. The value of such dispensaries and the important features in their conduct are discussed in an article by Dr. Edward O. Otis, Superintendent of the Boston Dispensary. The rest of the book is devoted to an account of the attempts which are now being made to provide special care for consumptives in hospitals for the insane and penal institutions, with articles by Dr. J. B. Ransom, of Clinton Prison, New York, and Dr. A. E. Macdonald, formerly Medical Superintendent of the Manhattan State Hospital East; a description of a municipal system for the control of tuberculosis, by Dr. Hermann M. Biggs, Medical Officer of Health of New York City, together with a summary of the measures which are now taken in the principal cities of the country; and, finally, statements of the methods of work and plans of the thirty-eight societies for the prevention of tuberculosis, immediately preceded by an article on the need for such societies, and their function, by Edward T. Devine, General Secretary of the New York Charity Organization Society. The Directory will be of value to every

physician and social worker and to every one who comes in contact in any way with persons suffering from tuberculosis. Orders may be sent, with one dollar, to the Charity Organization Society, 105 East Twenty-second Street, New York City.

PHILADELPHIA.

New Hospital Chartered.—A charter has been granted to the West Philadelphia General Homeopathic Hospital and Dispensary, at Fifty-fourth and Girard avenues. The building now has twenty rooms, but will be enlarged.

Medical Jurisprudence Society.—At the stated meeting of this Society, held Monday, December 19, a paper was read by Dr. Charles K. Mills. The subject was, "The Forms of Insanity Due to Alcohol and other Intoxicants, with Discussion of Some of their Medicolegal Relations."

College of Physicians.—A lengthy discussion at a recent meeting failed to result in deciding upon a site for the new building. A resolution authorizing the sale of the site previously purchased at Twenty-second and Ludlow streets was carried. The present site, to be increased by adjoining lots, is now meeting with most favor.

Endowment of University Gymnasium.—Great enthusiam was aroused at the exercises marking the completion of the new gymnasium of the University of Pennsylvania, by the announcement by Dr. White that a gift of $50,000 had been made. This amount was left by the late William Weightman, as an endowment in trust for the general advancement of physical education and athletics at the University. In honor of the donor the building will be known as Weightman Hall.

City Takes up Tuberculosis Problem.—Through the efforts of Dr. Lawrence F. Flick, the city has taken a step toward caring for its tuberculous population that is distinctly an advance. Director of Charities Martin has arranged for a special department for the care of the tuberculous at the Philadelphia Hospital and placed it in the hands of a staff of regular physicians. These are Drs. H. M. Landis, Joseph Walsh, Howard Anders, and W. B. Stanton. All are connected with the Phipps Institute and were chosen because of their experience with the disease. Each will have an assistant in the Philadelphia hospital work. Dr. Flick states that Philadelphia is now one of the best organized cities in the United States for the fight against tuberculosis.

The Canonsburg Medical Club. — Canonsburg, Washington county, enjoys the distinction of having one of the most unique Medical Clubs in existence. It meets every Saturday night, any time from 9:30 to midnight, alternately at some doctor's office. There is no constitution, no by-laws, no officers, no requirements connected with being a member, except that the member at whose office the club meets shall furnish the cigars. It has been in existence a year and is a pronounced success. It brings the doctors together for a talk, not necessarily medical, and the little petty things of the week that often rankle and sting, because misunderstood, are explained and not allowed to breed coldness. Doctors have enough annoyances without having any among themselves, and it is just wonderful how they are dissipated by a social cigar. If there were papers to read or duties to perform, the attendance might soon fall off.—*Penn. Medical Journal.*

Ideal House Described.—Dr. Robert E. Thompson, of the Central High School, in a recent lecture on "The History of the House," indicated some of the changes that will come in the house as based on a study of the above subject. The future house will contain no stoves or stairways. Housecleaning will be done by power, the dust being removed by a pneumatic exhaust system as is now in use in large hotels of modern construction. Streets will also be cleaned in like manner, the dust being removed to the country; in this way it may come to pass that country people will come to cities to get really pure air. The houses will contain elevators, heat will be supplied from a central plant and meals will be obtained from cooperative centers as is now done in certain parts of Norway. Moreover, the cooking will all be done by men who alone practice scientific cooking. Dr. Thompson incidentally said that women have no natural gift for cooking, their aim being to supply what people want instead of what is good for them.

Goiter in Pennsylvania.—In regard to the recent investigation of goiter in Northern Pennsylvania, especially Pike and Indiana counties, Dr. A. S. Ashmead writes an interesting letter to the *Public Ledger*. He has observed several cases in Pike county. In Indiana county, dwarfs and cretins are also found in the goiterous families. Dr. Ashmead says the air at the elevation of these counties is antituberculous, but there is a great strain on the circulatory and respiratory systems. The diet is mainly one of starches, and nearly every person has starch dyspepsia and a lazy temperament. Cardiac palpitation is brought on by slight exertion. The most important factor in the condition of the people, however, is that they have intermarried for many years. The thyroid shows the effect of overstrain in keeping such people alive and developing. Later the effect of this and intermarrying is seen in the appearance of dwarfs and cretins. These signs of degeneracy point to the fact that the mountaineer families in these localities are dying out; infusion of new blood is indicated.

CHICAGO.

Jewish Tuberculosis Hospital.—The building of a hospital for Jewish victims of tuberculosis has been urged by Mrs. M. J. Sturm.

To Aid Hospital Fund.—Nearly two thousand tickets have been exchanged for reserved seats for the Burton Holmes' Travelogue, "Round About London," which was given in behalf of the new Children's Memorial Hospital. Thirty boxes were sold.

Fight for Pure Drugs.—Cooperation in the prosecution of druggists who, in the future, dispense chemicals of an inferior quality was pledged by members of the Retail Druggists' Association at a meeting recently held. Resolutions were passed expressing regret that certain pharmacists have been inexcusably careless in selling spurious drugs.

Labor Unions to Join Fight Against the Spread of Consumption.—Labor unions have been enlisted to fight the spread of tuberculosis. The office janitors, cigar makers and garment workers recently offered their cooperation in efforts which are to be made to minimize dust in downtown buildings, and unhealthy conditions in shops and factories.

Preservatives in Food Products.—Dr. Edward Gudeman, at a recent meeting of the Chicago Section of the American Chemical Society, pointed out in a paper inconsistency on the part of the government in allowing the use of preservatives in imported foods, and agitating against them in home products. A label to mark artificially colored food was advised.

Mortality of the Week.—According to the weekly bulletin of the Department of Health, during the week ended December 10, there were 512 deaths reported, 35 of which were holdovers from November, making

the net deaths 477, and the annual death rate 12.89 per 1,000. Pneumonia heads the list with 85; consumption follows with 65; then come heart diseases and violence, 50 each, and Bright's disease, 41.

Annual Report of Chicago Lying-in Hospital.—The ninth annual report of this institution has just been issued. Besides $4.096 in cash donated by friends toward current expenses, the Associated Jewish Charities continued its subscription of $3,000 toward the expenses of the Maxwell Street Dispensary, and large additional sums were expended on the new building, which, with the land, represents an unencumbered outlay of $20,724.68.

Physicians for Work at Cook County Hospital.—President Brundage announces the nominating commission to select the attending staff of Cook County Hospital as follows: Drs. Chas. S. Bacon, Frank Billings, Daniel R. Brower, H. O. Brown, Sanger Brown, Thos. J. Conley, A. C. Cowperthwaite, Nathan S. Davis, Joseph B. DeLee, Fernand Henrotin, F. C. Hotz, Stewart Johnston, John B. Murphy, Hugh T. Patrick, Chas. E. Paddock, Wm. E. Quine, E. M. Reading, Nicholas Senn, Geo. F. Shears, H. M. Starkey, D. A. K. Steele, Jas. H. Stowell, Henry S. Tucker, Chas. S. Williamson and Casey A. Wood. The commission will proceed to select the membership of the staff at the County Hospital, and will present to the President of the Board their choice of candidates.

CANADA.

Annual Report, Toronto Home for Incurables.—The thirtieth annual report of the Toronto Home for Incurables states that there are at present in that institution 111 patients, 38 having been admitted during the past official year. Thirty-six deaths have occurred and twelve left the Home very much improved in health. The Training School for Nurses, established in January, 1903, has proved a success. The total expenses for the year amounted to $28,233.05. The inmates are divided into 57 women and 54 men. Of the former, the oldest is ninety years, and the youngest twenty-one. Of the men, the oldest is seventy-nine and the youngest seventeen. Of the total number paralysis claims 39 and rheumatism, 27.

New Brunswick Provincial Hospital for Insane.—A special commission, consisting of Dr. J. V. Anglin, the newly appointed Superintendent of the New Brunswick Hospital for the Insane, Dr. G. A. B. Addy and Dr. A. F. Emery, of St. John, have been examining the patients in this institution, the object being to relieve overcrowding from which the institution has suffered for some years past. There are at present 554 patients in the hospital, and a careful examination of all these is being made, so that the harmless insane may be removed to other institutions and thus provide accommodation for the more acute cases which can thus be better treated. Dr. Anglin will also press for reform in the matter of the admission of patients, and hereafter no patient will be sent into the hospital without the Superintendent first advising that there is proper accommodation for the care of such patient.

Alexandra Hospital, Montreal.—Through the generosity of Mr. James Ross, Montreal, the work of the erection of the Alexandra Hospital, Montreal, will be at once proceeded with. By the terms of agreement over a year ago the Trustees of the Protestant Hospitals of Montreal, were to have in readiness for the reception of cases of infectious and contagious diseases the new hospital to be known as the Alexandra Hospital. A site was secured at a cost of $90,000, but the erection of the building could not be proceeded with owing to the lack of funds. Recently the Hygienic Committee of the City Council of Montreal called a conference of the Trustees of the Protestant Hospitals, the object being to come to an understanding as to the cause of the delay. At this meeting it was decided to call a mass meeting of citizens and to procure contributions, when, if the proper response were forthcoming, work could go on and the new hospital erected for the reception of patients by September of next year. Dr. Roddick presided at this meeting, at which Mr. Ross promised $25,000 and other citizens handsome amounts, bringing the sum up to $62,500 available for the commencement of the work. When completed the hospital will cost in the neighborhood of $200,000.

GENERAL.

New Medical Building at Ann Arbor.—The ceremonies of laying of the corner stone of the new building for the Michigan College of Medicine and Surgery occurred on December 13. The edifice occupies a commanding site at the corner of the University Campus and is a worthy companion of its neighbors.

Plague Stops Army Coats.—The Governor of Viatka reports a serious outbreak of Siberian plague in factories in the districts of Viatka and Slobodski, which are preparing fur coats for the troops in Manchuria. Two hundred and forty-seven cases have already been reported. The plague has been traced to sheep skins, and the delivery of fur garments to the Russian troops has been suspended.

Patriotism in Hungary.—The Tuberculosis Sanatorium, named after the late Queen Elizabeth, proving too small to accommodate the hundreds of applicants, the committee resolved to erect two new sanatoriums in the healthiest regions of Hungary. In order to raise funds for this grand undertaking one million lottery tickets were issued at $1 each. The sympathy of the public for this measure has been so great that all the tickets were disposed of within one month. Premiums even were offered at double the price after the tickets were all sold.

Famine Threatened in Ireland.—With reference to the resolutions adopted at a meeting of the Irish Parliamentary party in Dublin, on December 16, calling upon the government to extend aid and institute works to afford employment for those in the West of Ireland who have been rendered destitute by the failure of the potato crop, the Irish Office here states that while there has been a partial failure of the potato crop in Ireland, government returns show that the distress, if it occurs, will not be acute before the end of January. Meanwhile the government is taking steps to prevent a famine.

Substitute Drug Poisoners.—Testimony by laboratory experts before the United States Commissioner's Court, sitting in Chicago, on December 17, in a hearing on criminal charges brought out the assertion that certain drugs sent about the country by alleged fraudulent mail order men endanger public life and health. Dr. John A. Wesener, of Columbus University, said a package which he had examined, marked as containing trianol, contained acetanilid. The substitution of acetanilid, grain for grain, for trianol, said the witness, "would in many instances produce acetanilid poisoning and death."

Fourth Pan-American Medical Congress.—The details of the program for the entertainment of those attending the Pan-American Medical Congress are as follows:—January 3.—On their arrival at Colon by special train the Medical Committee will receive the American delegates and accompany them across the isthmus. Registration will be followed by a reception

at the Presidential residence, and the opening session will be held in the evening. January 4.—Excursion and lunch, followed in the afternoon by section meetings with a banquet in the evening. January 5.—Excursion to Tabago Island and Panama Bay; in the afternoon addresses on hygiene, medical and surgical, and in the evening a ball at the International Club in honor of the delegates. January 6.—Excursion on the canal zone, visiting the great Culebra cut and important sections; in the afternoon a section meeting and the closing session.

New President of the Carnegie Institute.—Dr. R. S. Woodward, Dean of the School of Pure Science of Columbia University, New York City, was elected President of the Carnegie Institute, at a meeting of the Board of Trustees, held on December 13, in Washington. He will succeed Dr. D. C. Gilman, the ex-President of Johns Hopkins University, who has resigned. Dr. Woodward is well known as an educator and scientist, and when formerly in that city was connected successively with the Coast and Geodetic Survey and the Geological Survey. Dr. John S. Billings, of New York, and Dr. Charles D. Walcott, the Director of the Geological Survey, were re-elected members of the Executive Committee of the Board of Trustees. Dr. Woodward will not assume his new office until the close of the present university year, and perhaps not until later. Dr. Gilman, in his letter of resignation, gave as his reason for his action the fact that he had passed the age of seventy years and was looking forward to release from serious official responsibilities. He expressed his continued interest in the development of the institution, which, he wrote, "bids fair to be a most potent factor in the advancement of knowledge and in the encouragement of scientific men."

Dr. Howard's Joke on the President.—A recent call made by Dr. William Lee Howard, of Baltimore, at the White House, reminds him to relate this story: "A few years after Mr. Roosevelt left Harvard," said Dr. Howard, "I was living with his Harvard chum in bachelor's quarters on Washington Square, New York. We were medical students at Columbia University. My friend studied too hard and became very ill. There were some doubts about the diagnosis, so we were quarantined. The late Dr. Cyrus Edson and myself were left as nurses for the sick man. C.'s illness continued and was a puzzle to the many eminent physicians who called daily and who constantly congratulated Edson and myself on our faithfulness; but all seemed to forget that we were tired and hungry young men, and the little food we obtained at the restaurants around Washington Square was not to our satisfaction. Remember, C. had to be artificially fed on liquids. One day there was a gentle rap on the door, and upon opening it I was asked in a pleasant voice if C. W. lived there. Then he gently inquired after him, telling me to tell C. that he, Teddy Roosevelt, had called. As he turned to go he stopped and asked if there was anything he could do for C. How was he off for delicacies, wines, etc. Well, I jumped at the chance, and just what I told him I don't remember, but he certainly did not know much about illness, as on the following day there was delivered at our door a large hamper from Theodore Roosevelt, with a note expressing the hope that the patient would enjoy the good things. And those things were good—chickens, pates, guava jelly, hothouse fruit, champagne and Burgundy. Well, Edson and I did not go out for the frankfurters that day or the next. Three days later Mr. Roosevelt again called, and I am ashamed to tell what a con game I gave him about C. getting better; how the delicacies were devoured with eagerness—they were—and with such food C. would soon get well. Remember, the ill man was unconscious of all his surroundings and was being nourished by artificial means. Mr. Roosevelt went away, saying he would tell his sister to send down a hamper; also, some of his Harvard friends would be informed of what was needed. Well, Dr. Edson and I got so fat that by the time C. was able to be moved to Boston we had to get new clothes."

International Medical Congress.—Dr. J. H. Musser, President of the American Medical Association, at the request of the Secretary of the International Medical Congress, which meets in Lisbon in 1906, and on approval of the House of Delegates, has appointed the following members of the American Committee of Arrangements: Drs. Frank Billings, Chicago; Hermann M. Biggs, New York; Herbert L. Burell, Massachusetts; William T. Councilman, Boston; Wm. H. Carmalt, Connecticut; Richard C. Cabot, Massachusetts; N. S. Davis, Jr., Illinois; Chas. H. Frazier, Philadelphia; R. H. Fitz, Massachusetts; W. E. Fischel, Missouri; Chas. Lyman Greene, Minnesota; Ramon Guiteras, New York; H. A. Hare, Pennsylvania; L. Hektoen, Chicago; Edward Jackson, Denver; E. J. Janeway, New York; A. Jacobi, New York; George Ben Johnston, Richmond, Va.; W. W. Keen, Philadelphia; Howard A. Kelly, Baltimore; Chas. Kollock, South Carolina; L. S. McMurtry, Louisville, Ky.; James H. McBride, California; A. T. McCormack, Bowling Green, Ky.; K. A. Mackenzie, Portland, Ore.; John Herr Musser, Philadelphia; J. B. Murphy, Chicago; R. Matas, New Orleans; William Osler, Baltimore; Chas. Powers, Colorado; J. B. Roberts, Pennsylvania; W. L. Rodman, Pennsylvania; M. H. Richardson, Boston; Chas. A. L. Reed, Ohio; H. M. Sherman, San Francisco; Frederick C. Shattuck, Boston; Geo. H. Simmons, Chicago; Chas. G. Stockton, New York; Geo. Sternberg, Washington, D. C.; Victor C. Vaughan, Ann Arbor; John A. Witherspoon, Tennessee; J. Collins Warren, Massachusetts; J. C. Webster, Chicago; Wm. H. Welch, Baltimore; John A. Wyeth, New York; the Surgeon-Generals of the Army, Navy and United States Public Health and Marine-Hospital Service; the presidents of the American Ophthalmological, Otological, Gynecological, Physiological and Pediatric societies; the presidents of the American Dermatalogical, Laryngological, Surgical, Climatological, Neurological, Medico-Psychological and Orthopedic associations; the presidents of the Association of American Anatomists, Association of American Physicians, American Association of Genito-Urinary Surgeons, American Association of Pathologists and Bacteriologists, New York Academy of Medicine, College of Physicians, Philadelphia, Cook County Medical Society, Chicago, and the Society of Medical Improvement, Boston.

OBITUARY.

Dr. CLARENCE WILLARD BUTLER, one of the most prominent physicians of Montclair, N. J., died at his home in that place, December 20, from cancer. He was born in Bellevue, Ohio, in 1848, was educated in Oberlin College and the Homeopathic College in New York, and had been in active practice in Montclair since 1872.

Dr. CHARLES K. LAW, thirty-six years old, died at his home, 82 Glenwood Avenue, Jersey City, N. J., December 13, from peritonitis. He was a graduate of the University of New York and received his medical degree in 1893. He was a member of the University Club, the Jersey City Practitioners' Club, and of the Hudson County Medical Society.

Dr. CLARENCE S. ELEBASH died on December 20, after a three months' illness which originated in an attack

of typhoid fever. The fatal ending was feared, and his friends declared he was a martyr to duty. Dr. Elebash's city home was at No. 118 East Nineteenth Street, and he was a well known specialist in diseases of the eye. For years he was the head of the medical department of the Brooklyn Heights Railroad Company. He was forty-five years of age, a native of New York, and had practised in this city since his graduation from the New York University Medical College in 1891.

Dr. Samuel Hemingway, well known in New York a few years ago in medical circles, died December 18, from heart disease. He was fifty years old and a bachelor, and spent most of his time at his country place, in Oceanic, N. J. He gave up active medical work when only forty years old. When ambulance surgeons were new to New York, thirty years ago, Dr. Hemingway, who was then taking his hospital course after graduation in medicine, was one of the first. He was attached to the old Park Hospital, and made hundreds of runs on accident cases when hardly one out of a hundred persons knew that such a system was in operation and when the ambulance surgeon often had to battle for his own safety against the prejudices of ignorance in order to give needed surgical attention.

Dr. William M. L. Fiske, of Brooklyn, died December 21, at his home, No. 1140 Dean Street, that borough. His death was caused by an affection of the heart, from which he had suffered for four years. Dr. Fiske was born in New York in 1841. He first entered Bellevue Hospital Medical School, but left in 1862 to enlist in Company A of the Forty-seventh Regiment. He returned to the school later, and was gradnated in 1863, afterward graduating from the New York Homeopathic College in 1864. He was then appointed assistant surgeon in the United States Army, and served in that capacity till the end of the Civil War. Dr. Fiske was for many years president of the staff of the Brooklyn Homeopathic Hospital, and was one of the founders of the Eastern District Hospital. He was one of the organizers of the Training School for Nurses of the Brooklyn Maternity Hospital, and was president of the New York State Homeopathic Society. At the time of his death he was one of the Board of Examiners of the Board of Regents.

Dr. D. M. Echemendia, who died in Havana, Cuba, December 20, from a malignant fever, was formerly a noted yellow fever expert, and during the American occupation of Cuba did good work in driving the yellow fever from Havana. He was a surgeon of the United States Marine Hospital Service. During the Cuban revolution, in 1896, he was quarantine officer for the Florida State Board of Health, in charge of the Mullett Key station in Tampa Bay. On one occasion a Spanish cruiser passed the station en route to Tampa from Havana and paid no attention to the signal to stop and undergo inspection. Dr. Echemendia, who was a native of Cuba, became wrathful when he saw the ship flying the flag of the red and gold ignoring the orders of the State of Florida. He boarded the quarantine launch and overtook the cruiser before she reached Port Tampa. There was a lively interchange of compliments in the Spanish language, and the angry doctor ordered the vessel to return forthwith to Quarantine. The Spanish captain was indignant and protested that a State quarantine could not apply to a Spanish war ship. Dr. Echemendia was firm, and was backed by the State Health Office. The vessel later put to sea without touching at any Florida port. The Cubans in Florida have always declared that Dr. Echemendia was the only Cuban or American who ever captured a Spanish war ship single handed, and he was held in the highest esteem by them. Dr. Echemendia did good work in Florida during the yellow fever epidemics in 1887 and 1888.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, December 3.

THE GENERAL MEDICAL COUNCIL—THE SCOTTISH UNIVERSITIES—BRITISH NEGLECT OF SCIENCE—THE HEALTH OF THE NAVY—MISCELLANEOUS.

Dr. Donald McAlister, of Cambridge, has been elected President of the General Medical Council in succession to Sir William Turner who has, like Cincinnatus, returned to his cabbages. Dr. McAlister, who must not be confounded with his more famous cousin, Dr. Alexander Macalister (the difference in regard to the "Mac" has been adopted by mutual consent for the purpose of differentiation) who is Professor of Anatomy in the University of Cambridge and a learned Egyptologist besides. Dr. Donald McAlister distinguished himself as a student by coming out at the top of the Mathematical Tripos. There is nothing that Cambridge venerates so much as a Senior Wrangler, the name given to the first mathematician of the year. There is a story that a man who had achieved that greatest of academic honors celebrated his triumph by going to the opera. He entered a box just as some august Royal personage entered one on the other side of the house. The audience cheered as is the wont of Britishers when royalty condescends to honor an entertainment with its presence. The Cambridge man, with all his blushing honors fresh upon him, took the applause as intended for himself and bowed most graciously, whispering at the same time to his friend "I did not think they could have known of it already!" Cambridge men take this story seriously and check the laughter of the profane by saying that it was a very natural mistake as it is quite right that a Senior Wrangler should receive royal honors. Dr. Donald McAlister has lived at Cambridge all his professional life. He has not made any particular mark as a physician, thus verifying, to some extent, the common saying that Senior Wranglers are never heard of in after life. He was, it is understood, bitterly disappointed that he was not appointed Regius Professor of Medicine instead of Dr. Clifford Allbutt. He has, however, a considerable academic position. He is Linacre Reader of Physic in the University and Senior Tutor of St. John's College. He has the reputation of a first-rate man of business. He has represented his University on the General Medical Council for a number of years and his influence has always made for moderation and statesmanlike breadth of view in the deliberations of that assembly. His sober good sense has been as a brake to the reckless driving of Sir Victor Horsley. The latter is a type of the *idéologues* so despised by Napoleon. Such power as he has is destructive; McAlister, on the other hand, is nothing if not practical and constructive. It is owing mainly to him that Horsley, who entered the Council as a kind of elemental force, amid the shouts of the professional Demos, is now, to use Disraeli's phrase, an almost extinct volcano. It is rumored that at the end of his term Horsley will not offer himself for re-election. This, if true, may be taken as a confession of failure.

One of the matters debated by the General Medical Council was a report by the visitors and inspectors of the Council, on the final examinations of the University

of Edinburgh. In that report the inspectors "felt obliged to criticize unfavorably some of the arrangements and methods of the examination in clinical surgery." Attention was called to the ignorance of surgical pathology shown by the candidates, to their apparent want of training in clinical observation, and to their lack of practical skill in operative surgery. Summing up their conclusions the inspectors remark that "it is to be assumed that the University authorities desire the degree to be a high one; at present this can hardly be said to be the case." The report led to a heated discussion in which Sir William Turner descended from the Olympus of the presidential chair and entered the arena as a combatant in defence of the University of which he is the representative. Sir John Batty Tuke, another Edinburgh man, also flourished his claymore at the audacious "Southrons" who dared to breathe a word against the fair fame of Scottish universities. The inspectors, however, stuck to their guns. It was an amusing though not altogether an edifying scene. The Scottish thistle is proverbially not to be handled with impunity and the Caledonian stern and wild is especially touchy about his universities. He has good reason to be proud of them but he insists on their being regarded as sacred. The University of Edinburgh in particular, looks upon itself as sacrosanct—indeed as an ark of the covenant not to be touched by profane hands. A year or two ago the *British Medical Journal* published a letter in which it was hinted that the teaching in that famous seat of learning was not all that it might be. The same thing was being freely said in much stronger terms in the Edinburgh papers, but it was felt to be an intolerable insult that any criticism of a Scottish institution should appear in a journal published in England. The heather was on fire, and Edinburgh men clamored for some one's head. Many years before the same journal had allowed itself to indulge in some extremely gentle criticism of the University of Edinburgh, and the offence has never been forgiven. At any rate this is the explanation given of a certain aloofness in regard to the British Medical Association, which has become traditional in the city that delights to call itself the "modern Athens." As for the report of the inspectors of the General Medical Council, rightly interpreted, it is a thing of little moment. As has been said in former letters, a system of reprisals has been in vogue for some time past, which goes far to deprive these reports of any real significance. English inspectors have adversely criticised the examinations of Irish Universities and Colleges. Irish inspectors have retaliated by condemning English universities, including even Oxford and London. Scotchmen have given thanks that their schools were not even as those of the English and Irish. This pharisaic attitude has had its natural result. The true value of the criticisms of the surgical examinations of the University of Edinburgh may be gathered from the fact that the inspector, Mr. Thomas Bryant, formerly Surgeon to Guy's Hospital, has not, it is said, been inside a surgical ward for fifteen years. Only a few years ago, speaking of the same University, he reported that the entire examination in clinical surgery was a most complete, searching and practical one." A frank account of the more recent experience which has led him to change his mind would be interesting.

The annual dinner of the students, past and present, of the Medical School of the University of Birmingham, took place on November 30. Sir Frederick Treves, in proposing the toast of "The Medical School," said it used to be considered that a university could not be good unless it was old and located in some quiet place far from the haunts of men. But times have changed. A university, to be a success in science, at any rate, must be young and must be situated in a great city like Birmingham. Whatever the theoretical value of Latin and Greek, the thing of absolute importance in these days was applied science. It was to be regretted that very little heed was given to science in this country. All the great advances in medicine and surgery had been made by men who had worked for positively nothing and had made a present of their discoveries to the world. There was a sort of Free Trade practice which left the medical discoverer at the mercy of everybody. It would be a very good thing if some kind of fiscal policy could be introduced by which those who taught science in this country could be placed in a similar position to that occupied by those in Germany or America. Mr. Chamberlain (Chancellor of the University), who proposed the toast of "The Past and Present Students of the Medical School," said he had never seen so many medical students together before. He had been examining them with great interest. He thought there was a lingering suspicion in the minds of the public that as a class they might still be considered as fairly represented by those world-known portraits of Mr. Bob Sawyer and Mr. Benjamin Allen. But if that was the public view the public were very much mistaken. He went on to say that three classes of people were essential to the success of a modern University. There were, first, the students, who would always be with us. In the second place, there were the teachers. It was upon their energy, their capacity, their knowledge, and their distinction that reputation of the University would always depend. Lastly, there was a third class, and the third class was at least as important as the other two. That was the class that was known as the "pious benefactor" that was a species which was undoubtedly much too scarce in these days. In the United States, through munificent donations to be counted by millions, they had covered the land with a network of Universities which had brought higher education within the reach of almost every citizen. He hoped the time was coming when those in this country who had more than they wanted would be content to dispose of more of their wealth in the shape of contributions to such institutions. He had heard—he did not know whether it was a superstition—that sometimes gentlemen in the medical profession were consulted by their patients and friends as to the disposal of such surplus. If it were the fate of any past or present student to enjoy such confidence he hoped he would gently insinuate that, if his patient or friend desired undying renown and the gratitude for all time of generations to come, he could not do better than to enable them to supply what was at present their greatest deficiency and to establish in Birmingham in connection with their University a great medical school of research.

The Director-General of the Medical Department of the Navy, in his annual report to the Admiralty, issued on November 28, states that the aggregate number of cases of disease and injury recorded last year furnished a ratio of 831.57 per 1,000, which showed a decrease of 29.56 per 1,000 compared with the ratio of 1902, and a decrease of 48.06 contrasted with the average of the last six years. The invaliding ratio of the total force—viz., 24.03 per 1,000—showed a decrease of 5.93, and the death rate, which was 4.19, showed a decrease of 1.73 per 1,000, and was the lowest recorded since 1856. Only two wounds in action are recorded, with one death, which occurred on the East Indies Station, when the Mohawk landed a force to punish the chief of the

village at Durbo, Italian Somaliland. The total force serving afloat last year was 103,100, the total number of men sick daily was 3,633.54, and the total days' sickness on board ship and in hospital was 1,326,244, representing an average loss of service from disease and injury of 12.86 days for each person. Enteric fever shows a slight increase of .15 per 1,000 of cases, but the deaths during the year were fewer by seven than in the preceding year. Ten cases of plague are recorded as having occurred on the China Station, none of which proved fatal. There was only one case of cholera. There were 17,295 cases of wounds and injuries and 129 deaths, as compared with 16,389 and 225 deaths in the previous year. Sixteen men committed suicide.

The King has subscribed $250 and the Queen $500 to the fund being raised by a British Committee toward a memorial of the late Professor Finsen, of Copenhagen.

Dr. A. W. Wigmore, who went through the Bankruptcy Court the other day, stated that he was an X-ray expert, and attributed his failure to the "slump" which has taken place in that line of practice owing to the scare (referred to in a recent letter) produced by the reports of injurious effects caused by the Roentgen rays that have appeared in the newspapers.

Dr. Achille Vintras, founder of the French Hospital in London, who died two or three weeks ago, was a highly respected physician, in speaking of whom the epithet "blameless" applied by Homer to prophets, naturally rises to the lips. He was the son of a somewhat remarkable man who, if not blameless, claimed to be a prophet. Vintras *père* was the son of a washerwoman of Bayeux in Normandy. After a youth of poverty and adventure he heard voices which told him he was the prophet Elias. He founded a new religion, but less fortunate than Dowie, his tub-thumpings alarmed the French Government, and he was put in prison where he remained till 1848; the personal intervention of Crémieux was required to set him free. Disgusted with his inappreciative countrymen he founded a church in England, but went back to France where he died in 1875.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, held November 16, 1904.

The President, John B. Murphy, M.D., in the Chair.

Advantage of Muscle-Splitting and Muscle-Retraction Incisions in the Prevention of Ventral Hernia.—Dr. Martin B. Tinker, of Ithaca, N. Y., read a paper (by invitation) on this subject, saying that the very considerable number of ventral hernias, following clean, uncomplicated abdominal operations, which probably come to the notice of every surgeon in active practice, should furnish ground for reflection as to the necessity for their occurrence. The number of these cases, which have come to him during the past year, has formed almost four per cent. of his total number of cases, and his previous experience has led him to believe that the patients seldom return for the cure of their hernia to the surgeon who performed the original operation causing the hernia. The state of many of these patients, with their constant discomfort from wearing some form of abdominal support, with pain from adhesions about the hernial opening, and with the not infrequent occurrence of symptoms of strangulation, often makes their condition but little preferable to that for which the original operation was undertaken. To avoid the disadvantages of the rectus incision, especially the paralyzing of the median side of the muscle, Lennander in 1898 introduced the rectus retraction incision. In 1900 Pfannenstiel introduced his supra-symphysarian cross incision, which gives free access to the pelvis and organs near the median line of the body. In opening the abdomen for pelvic operations of any kind, the speaker usually employs the Pfannenstiel incision, although if freer exposure is desirable, the Lennander incision is preferable. The Pfannenstiel incision has the possible additional advantage of placing the scar below the pubic hair line, where it is not noticeable. It will be found very satisfactory for myomectomy; operations on the tubes or ovaries; advancement of the round ligaments for backward displacement, or other operations near the median line of the lower part of the abdomen. For abdominal hysterectomy the Lennander incision gives better exposure. For exploration of the right iliac fossa, where some involvement of the pelvic organs is suspected, he also prefers the Lennander incision. Where simple appendectomy is to be performed, he thinks nearly all surgeons agree that the McBurney muscle-splitting incision is preferable, but when appendectomy is combined with work in the pelvis, the Lennander incision is preferable. Operations in the upper abdomen are far less likely to be followed by postoperative hernia, but, as Richardson recently pointed out, the muscle-splitting incisions in the treatment of diseases of the gall passages afford far greater security against the occurrence of ventral hernia. There are undoubtedly other features of great importance in the prevention of ventral hernia. Healing by first intention is of first importance; the specially careful arrest of hemorrhage to prevent accumulation of blood in the wound, not only lessens the danger of infection, but favors firm healing. The prevention of strain on the wound after operation by distention is also very important. Undoubtedly the accumulation of intestinal gases can be greatly lessened, if not entirely prevented in most cases, by thoroughly emptying the intestinal tract before operation, and by careful attention to the bowels after operation. The avoidance of any strain on the wound by preventing postoperative nausea and vomiting was important, also the prevention of strain on the wound by the patient exerting himself too early. The possibility of getting the patient out of bed at an early date following operation with a feeling of absolute security from hernia, and without the necessity for wearing a binder, is a great satisfaction and sufficient reward for the extra pains and few additional minutes of time required to open and close the abdomen by any one of these methods.

The Kocher Method.—Dr. L. L. McArthur thinks that to Kocher, above all modern teachers, is due the credit for presenting in a systematic manner the best lines of incision to follow. These are prettily illustrated in his work on operative surgery, particularly in the early editions thereof, in which he describes the lines of cleavage. These lines of cleavage bear a relationship always to three factors, to those lines in which the least tension would occur, to those in which the least destruction of muscular fiber or actual paralleling of muscular fiber will occur, and finally an important factor of those incisions in which the innervation of these muscles involved shall not be disturbed. He is very much surprised that in any man's statistics, on careful investigation of the through-and-through suture in the linea alba in uncomplicated cases, where drainage has not been necessary, that as large a per cent. as one in five, or twenty per cent. of the hernias, should occur. It may be explicable on the basis that patients do not return to the surgeon who has been the cause of the

hernia. He thinks a very decided improvement on an incision known as Kämmerer's is one at the edge of the rectus, where occasionally one finds it necessary to go into the pelvis for complications in operations which are associated with appendical work, as, for instance, ovarian tumor, suppurative tubes, twisted ovarian pedicle, etc.

Dr. Bevan's Procedure.—Dr. Arthur Dean Bevan agreed with the essayist as to the importance of planning incisions so as to reduce the dangers of resulting postoperative hernia to a minimum; but there are a number of factors which must be considered in planning an abdominal incision. First, and most important, is to plan the incision so as to give free and sufficient exposure to do the operation. Second, plan the incision so as to give the least possible danger of a resulting hernia. If one is opening the abdomen to remove a large fibroid of the uterus, he could not employ the Pfannenstiel incision. If he is opening the abdomen to remove a large spleen, he cannot employ the muscle-splitting incision. If he is opening the abdomen posteriorly, to remove a large tumor of the kidney, the muscle-splitting incision is out of question. Furthermore, if he is opening the abdomen to operate upon the common duct, the muscle-splitting incision is out of the question, and should not be considered. The muscle-splitting incision has little value in operations on the kidney. An incision can be planned for the exposure of the kidney which is parallel with the nerves of the region of the abdominal wall, and yet not be a muscle-splitting incision. There is very little danger of hernia in a properly planned kidney incision, which divides the external oblique, the internal oblique, and transversalis fascia, but which does not interfere with the nerve supply or arterial supply of the abdominal wall posteriorly. Incisions in the posterior portion of the abdominal wall, and the upper portion of the abdominal wall, are not nearly as apt to be followed by hernia as incisions in the lower portion of the abdominal wall. An oblique incision parallel with the costal arch in the upper abdomen, which divides nerves, muscle fibers, or fibrous tissue transversely, is not nearly so apt to be followed by hernia as a muscle-splitting incision in the lower portion of the abdominal wall. It is rare to have a hernia following an incision parallel with the costal arch for gall-bladder work. He is very fond of muscle-splitting incisions, and employs them wherever he can do so. He does not think, however, that the point should be emphasized to employ these incisions where other factors are more weighty. An incision in the median line, in the linea alba, is a very safe and useful one, and he employs it quite extensively. He thinks that the statistics of seven per cent., or twenty per cent., are altogether too great. Why should one have a hernia in a midline incision of from three to six inches in length which heals by primary intention, and where the patient has been allowed to remain in the recumbent position until wound healing is complete? He is rather impressed with the fact that the German surgeons have more hernias following their operations than American surgeons. He called attention to the fact that the statistics of operations, for instance, from the Heidelberg Clinic, by Czerny, which have been extensively reported in the *Beiträge zur klinischen Chirurgie* for the last four or five years, show the proportion of hernias to be from 20 to 25 per cent. in suppurative cases. This percentage would be considered large in America. The length of the incision is of comparatively small importance as compared with primary wound healing. The recumbent position should be maintained until wound healing is complete. He has no sympathy whatever for the proposition of having a patient get up on the second day after a muscle-splitting incision or not.

Dr. E. Wyllys Andrews said he had supposed until recently that the Pfannenstiel incision was a skin incision only. He has only used it a few times, and believes it is used almost solely in the case of young women, and generally unmarried women so as to be covered by the pubic hair afterward. Personally, he likes to go one-half or three-quarters of an inch out from the median line and secure muscular wall for the incision. He attaches a good deal of importance to the imbrication idea even in ordinary celiotomy.

German Statistics.—Dr. A. J. Ochsner agreed with the previous speakers regarding German statistics, and said whoever has witnessed these clinics, from which these statistics were taken, knows that several things were done which must result in bad unions. First, the incision is made very long usually; second, the tissues are handled roughly; third, the stitches are applied with the least possible amount of care and accuracy; fourth, they are tied so tightly that they tend to cause pressure necrosis. All of those factors were bound to cause ventral hernia. He ventured to say that there is not one-fourth of one per cent. of ventral hernia possible, provided the conditions he had mentioned were carried out. He has followed many hundreds of his cases, and in those in which there was no drainage or suppuration there was no ventral hernia. One cannot get a ventral hernia if the different layers are accurately and properly approximated. He places a silkworm-gut suture down through the transversalis fascia as an emergency suture, so that if the patient should sneeze severely at the time when the catgut has become softened, there will be a safety suture on the outside to hold it. He sutures the peritoneum and transversalis fascia together; he passes a second catgut suture through the muscle, and a third catgut suture through the aponeurosis of the external and internal oblique, and after all ties the silkworm-gut suture sufficiently loosely to guard against pressure necrosis. Furthermore, he applies for emergency's sake again broad adhesive strips, so that if the patient should strain, vomit severely, or sneeze, the soft tissues would not be torn. He takes the additional precaution of always emptying the bowels thoroughly before operation, and of keeping them moved always so as not to cause a great amount of intra-abdominal pressure.

The Median Incision.—Dr. E. C. Dudley said the probabilities are that the most practical single incision for exploration is one that is made near the median line. He is inclined mostly to use a median incision and a lateral median incision for pelvic work and for appendicitis work, with a lateral incision for simple appendicitis work, and an incision in the region of the gall-bladder, because the greater part of his surgical work has been done in these three regions. He makes his so-called median incision through the right rectus muscle, parallel with the fibers of the muscle, somewhere near the inner margin of the muscle. This is done in order to avoid ventral hernia or to get a more accurate closure. For many years he has abandoned the through-and-through suture, and has used chromicized catgut, suturing layer by layer, first the peritoneum, the posterior fascia, the anterior fascia over the rectus muscle, and then, if there was a great deal of subcutaneous structure, sutures through that, and then inserts a buried suture for the skin.

Dr. William Cuthbertson stated that Pfannenstiel recognizes the limitations of his own incision, which is applicable to the removal of large tumors or of ap-

pendices complicated by some pelvic difficulty where there may be a short mesoappendix or cecum. He agrees with Dr. Bevan in reference to the after-treatment. One point seems to be lost sight of by some practitioners, namely, the complete wound healing after operation in the abdominal cavity. The experiments he has made on dogs in the past directed his attention particularly to this fact, that after having opened the abdomen of the dog, forty-eight hours later, it was quite easy to open the wound by simply pressing the finger through the line of incision. In from four to five days it was hard to open the skin incision with the finger, and it usually required the handle of a scalpel, a Kocher dissector, or a moderately sharp instrument to reopen the skin incision. After having gotten through the skin, it is an easy matter with the finger to separate the abdominal muscles and reenter the abdominal cavity. In all cases of abdominal operations we should not be in such a great hurry to get patients out of bed unless they are old and feeble, but to give them a longer time to let wound healing be complete. Furthermore, to have thorough hemostasis before closing the abdominal wound, and not leave so much blood clot between the surface of the wound to become organized.

Dr. Carl Beck has had experience with the incisions of Pfannenstiel and Küster. German surgeons publish a larger number of statistics than do Americans, because they keep more exact clinical records. If patients in America have hernia they do not return to the clinics as do the patients in Germany, and consequently hernias do not appear to American surgeons as such afterward, but they go to other surgeons. The percentage of hernia, therefore, following operations in America is much greater than would appear from what has been said. Secondary union is largely due in many instances to poor hemostasis in closing the abdomen. Blood clots are formed, and there are accumulations of blood which, with germs or foreign bodies in catgut or silk, cause an aseptic suppuration, and from this secondary union takes place. He has removed large tumors through a small transverse incision because one can stretch the incision. The muscles are not split, but simply the fascia. There is one disadvantage connected with this method, namely, that large surfaces are opened, and if exact hemostasis is not applied secondary union is invited, which can be avoided in the other incision by putting in a number of sutures of catgut or of silk. Formerly he had a number of suppurations, but latterly he had been able to avoid this by putting in drainage in the septic cases clear down to the surfaces that had been divided. With the addition of tubal drainage, one can employ this incision satisfactorily, and can avoid hernia.

Dr. Albert Goldspohn said, his own impression is that the percentage of hernia is far less than that mentioned, and from his own experience he was inclined to regard it as almost a closed chapter. The cardinal principles of closure of wounds must be carried out, or there will be a hernia. He described a technic similar to that of Dr. Ochsner, with the exception that he does not find it necessary to open the sheaths of both recti, but severs one rectus muscle and opens one sheath only, not splitting the muscle, but separating it from the linea alba, and then uniting it with a few through-and-through sutures to guard against the accumulation of serum or of blood between the layers of the wound.

Dr. Tinker, in closing, said he would not have any of the members believe that he advocates these incisions for all kinds of surgical work. No one recognizes their limitations any more clearly than he does. He also agrees with the gentlemen that certain operations cannot be performed with the use of the incisions which he had advocated. The Pfannenstiel incision has many of the advantages he had spoken of. It is not his custom to allow patients to get up in less time than a week, and usually not until ten days after operation. Healing is not likely to be complete until that time; but he does feel perfect confidence in allowing a patient with one of these incisions to get up at the end of two weeks at the latest, without the use of any binder, and he has yet to see any evil results following it.

NEW YORK NEUROLOGICAL SOCIETY.

Regular Meeting, held November 1, 1904.

The President *pro tem*, Joseph Fraenkel, M.D., in the Chair.

Two Cases of Bilateral Symmetrical Atrophy of the Thenar Eminence.—These were presented by Dr. I. Abrahamson. The first patient was a woman, sixty-two years old, whose family and personal history was negative. Her occupation was that of a housewife, which necessitated putting her hands in water a great deal, and she also assisted her daughter at needlework. Eight years ago she first began to experience numbness and paresthesia in both hands, with beginning atrophy of the thenar muscles, chiefly the flexor brevis pollicis. There were no trophic skin changes and no nerve tenderness. The atrophy was symmetrical in both hands. The second patient was a woman, fifty-two years old, a native of Hungary. Her occupation was that of a housewife. The symptoms were similar to those in the first case, but the paresthesia was most annoying at night. There was marked symmetrical atrophy of both thenar eminences. The speaker said he regarded both of these cases as examples of acroparesthesia with subsequent atrophy.

Dr. Charles L. Dana said the unusual feature of these cases was the symmetrical character of the atrophy affecting both hands. Not long ago, the speaker said, he saw a case of atrophy of the thenar eminence of one hand, with paresthesia and evidence of neuritic disturbance. In this instance, the condition had been produced by the Vardon grip in playing golf. In another case the patient was an elevator boy, and the neurosis had been produced by pulling on the wire rope of the elevator. While these occupation neuroses were not particularly rare, bilateral and symmetrical cases of this kind were extremely so.

DISCUSSION ON THE CLASSIFICATION OF THE MELANCHOLIAS.

Dr. Charles L. Dana opened the discussion. He stated that the term melancholia indicated to the psychiatrist a combination of symptoms varying in groupings, duration and intensity, but beneath all a dominant condition of painful emotional depression. It might occur as a symptom in various organic and degenerative cerebral diseases, but it was recognized in particular as a manifestation of two the period of involution of change of life and later. Second, that occurring in early and early middle life. No one, the speaker thought, disputed the distinctive character of melancholia of the first type as it occurred in middle and late life. The "melancholia of involution" was a chronic and incurable disorder. It was a psychosis accompanied with anxious, worrying apprehension, and was often a natural evolution of the constitutional worrier. It

was characterized by hypochondriacal and obsessive ideas, dysthesia and somatic delusions; by hallucinations, self-accusations, and at times by suicidal ideas and impulses. There was complete self-absorption, narrowing of consciousness, enfeebled attention and power of concentrated or constructive thought. There was no clouding of consciousness nor retardation of thought nor dementia. It was an agitated, worrying hypochondriacal psychosis. The melancholias which were seen especially during early life, and were at least characteristic of that period, had not such a single definite picture. That form which had been described as acute melancholia, however, was in its typical form a sharply defined condition, characterized by profound emotional depression, retardation and difficulty of thought, clouding of consciousness and other phenomena familiar enough to all. This form of melancholia, so Kräpelin and his followers teach, was not really melancholia, but only the melancholic phase of manic-depressive insanity, and it was proposed to substitute this term for all or most of the functional melancholias not belonging to the melancholia of involution. Hence we would have but one real melancholia, the chronic form of later life. Dr. Dana said he had been trying to fit this scheme to his experience, and for that purpose he had looked over the histories of over 400 cases occurring in his private practice. Of these he had closely analyzed 30, which he had seen more recently and in many instances followed for a long time. From this analysis he had reached the conclusion that chronic melancholia, under the classification of Kräpelin, was indeed a special disease, but not in all cases one of the involutional period. In its milder types especially, it seemed to him that pictures of it would be called anxiety psychosis, or depressive neurasthenia, and it was not unreasonable to suppose that in psychopathic individuals, or those with a special hereditary tendency, the nervous system should be subject to early chronic melancholia. He thought it possible that this same worrying psychosis might appear at the period of adolescence, when the disease was less intense, the somatic and sensory disturbances less severe, but the mental state essentially the same. The sharply defined delusional melancholia of early life, with great activity of thought, clearness of memory, intense self-accusation and powerful suicidal impulses belonged more to this type than any other. The association and alternation of mania with early, simple recurrent melancholia was an established fact, and the term manic-depressive insanity fitted this group of cases admirably, but in the speaker's list of 400 cases of melancholia, mostly not asylum types, there was a history of mania in only eight per cent. It seemed rather forcing the issue, therefore, to use the term manic-depressive insanity for these patients, who never had any mania. He was inclined to regard the melancholias of early life as simple melancholias of the involution type—or pre-involutional, if that seemed a better term. He would, at least, consciously associate their disorder to that form seen more typically and severely later in life. He would say that there were a great number of simple, functional, often recurrent melancholias that belonged to the manic-depressive type by reason of the neurasthenic and apathetic condition, the absolute loss of interest in life, and psychomotor sluggishness and enfeeblement, but he saw no reason to use the term manic-depressive insanity here. He would only use the term manic-pressive insanity when there was evidence of it.

Dr. M. Allen Starr said that Dr. Dana's remarks regarding melancholia would appeal to every neurologist and practitioner who did not constantly come in contact with the severer types of insanity. Those who were doing asylum work, however, might meet with considerable difficulty in grouping certain of the cases. Perhaps five per cent. of the cases in the average asylum could not be positively assigned to any definite group. The speaker said he was glad to hear Dr. Dana make a distinct protest against the term manic-depressive insanity. He had never been in sympathy with that term, for the simple reason that it did not coincide with our clinical experience in this country. He had carefully reviewed the records of about 280 cases that he had classified as melancholia, and he saw no reason to protest in any way aginst the classification that was proposed by Krafft-Ebing years ago, namely, simple melancholia, melancholia with delusions, and melancholia with delusions and agitation. Those three types embraced distinct varieties of the disease. The speaker said he also agreed with Dr. Dana that the type that rose to the stage of mania was extremely rare, in his own experience probably not exceeding five per cent. of the total number of cases observed. He thought it would be very unfortunate, therefore, to label these patients with a term like manic-depressive insanity, in spite of the fact that in 95 per cent. of the cases there was no mania whatever. Dr. Starr said that a careful study of his cases of mild melancholia had impressed him with the idea that the condition was a purely toxic neurosis. The symptoms were most severe in the early morning, and passed off largely during the day. Sixty per cent. of his cases never passed beyond the simple melancholia type, which was not the type met with in the insane asylums. The cases he had in mind were entirely conscious of their surroundings and of their own condition; they were in extreme dread of insanity, and they were not suitable subjects for an insane asylum and to incarcerate them in such an institution would be an outrage. About 35 per cent. of his cases correspond to the delusional type, and required watching to prevent suicide. Dr. Starr said he would like to impress upon the Society the existence of a true toxic melancholia. In fully 60 per cent. of his mild cases he believed that he had to deal with a purely toxic neurosis, and if we could eliminate the poison, we could cure the patients. He had noted that any intercurrent disease, such as grippe, pneumonia or malaria, that produced a decided change in the chemistry and nutrition of the body, arrested the symptoms in these mild cases of melancholia, and he had produced the same effect by the use of thyroid extract. Under the administration of this agent the symptoms of melancholia would be immediately relieved and remained absent until the temperature again dropped to normal.

Depression Instead of Melancholia.—Dr. Adolf Meyer said that his experience with the melancholias had naturally been of a different sort from that of Drs. Dana and Starr, having been largely confined to patients who were already committed to the asylum. His observations had led him to conclusions which did not essentially differ from those of Dr. Dana, although for practical reasons he would rather favor a different classification. On the whole, he was desirous of eliminating the term melancholia, which implied a knowledge of something that we did not possess, and which had been employed in different specific ways by different writers. If, instead of melancholia, we applied the term depression to

the whole class, it would designate in an unassuming way exactly what was meant by the common use of the term melancholia; and nobody would doubt that for medical purposes the term would have to be amplified so as to denote the kind of depression. In the large group of depressions we would naturally distinguish our cases according to etiology, the symptom-complex, the course of the disease and the results. A distinction into acute and chronic forms is not consistent with experience. Dr. Hoch finds that all attacks tend to become longer in advanced years. The distinction had best be made according to the intrinsic nature of the depression. From that point of view we might distinguish the pronounced types from the simple insufficiently differentiated depressions. Besides the manic-depressive depressions, the anxiety psychosis, the depressive hallucinations, the depressive episodes of dementia praecox, the symptomatic depressions, non-differentiated depressions will occur; especially the differentiation of the dementia præcox type frequently causes difficulty, where stupor and catalepsy supervenes. The speaker said he was somewhat surprised that no reference had been made to the difficulties in determining the depressions of dementia præcox. He took exception to Dr. Starr's statement that mania was but a rare event and only to be expected in the most agitated cases. He could not recall a single instance where a case of the pure agitated type developed mania, while on the other hand, the type that did not show the agitation, but a great deal of inhibition and subjective inadequacy—was the form that might develop mania. Dr. Meyer said that he would rather hesitate to accept Dr. Starr's idea that the intermission in the symptoms of melancholia produced by febrile disturbances proved the toxic origin of those symptoms, because an intercurrent disease was apt to produce a change in the symptoms of almost any mental disorder. The shortness of the time for discussion did not permit the review of about 300 cases of depressions to be reported on another occasion.

Classification of Insanities.—Dr. Ralph L. Parsons said that some years ago he made out a classification of the insanities that was provisional only, because the facts upon which to construct a scientific classification did not exist then nor did they exist at the present time. Different types of insanity were often very closely identified, and during the same attack the patient might exhibit symptoms of mania-melancholia and dementia. Dr. Parsons then exihibited a table that he had devised, in which the melancholias were divided into many different types descriptive of their cause, such as adolescent, puerperal, etc.

Remarks on Melancholia.—Dr. Joseph Collins said that while some writers on mental diseases claimed that melancholia was a very uncommon disease, and much less frequently met with to-day than mania, others maintained that there was no such disease as melancholia, and that that which we called melancholia was a symptom of a diagnosticable condition, which, being the real disease process, should be entitled to the name. Personally, Dr. Collins said, he was in sympathy with the latter writers, insofar as their position compelled them constantly to seek for the dependency of melancholia, but he was unwilling to accept their statement that there was no such disease as simple melancholia, *i.e.*, melancholia which was not a constituent of other disease, physical or mental. The general practitioner was likewise loath to accept such statements, because they seemed to him to be at variance with his experience. The difficulty in discussing the subject was that the term melancholia was used by writers with great latitude and absence of specificity. Melancholia, or mental depression, coupled with moral insufficiency, sadness and anguish, was of common occurrence. It was encountered in certain toxic states, such as alcoholism, and as the result of insufficient oxidation and deficient elimination. It was found associated with neurasthenia, paresis, general and cerebral arteriosclerosis, dementia præcox and mania, and also occurring without any of these associations. Every neurologist saw a great many cases which he diagnosticated as melancholia without being able to satisfy himself of the dependency of the melancholia, just as the general practitioner or consultant in internal medicine must often still make the diagnosis of indigestion without being able to satisfy himself that it was dependent upon one or more of a number of disorders conditions that were sufficient to cause it. When the neurologist had the opportunity of observing these cases for a protracted time he was unabled to classify them more specifically, and from an etiological standpoint more correctly. There was a tendency at the present time to put all cases of melancholia that could not be referred to organic disease and manic-depressive insanity under the head of "involution melancholia," *i.e.*, melancholia associated with retrograde changes in the tissues, and occurring at a time in life when such changes of the tissues set in physiologically, and therefore directly or indirectly dependent upon them. It was the writer's experience that considerably less than one-half of all the cases diagnosticated as melancholia, using the term in the specific sense mentioned above, could be placed in this category. Dr. Collins then cited, in detail, a number of cases of melancholia which illustrated the great variation in the onset, delineation and course of the disease, and the difficulties that beset the attempt to place them in one or two groups. The neurologist often had much difficulty in deciding whether such a case should be called neurasthenia, hypochondria or melancholy depression. Some of these cases eventually became insane (using the term in its legal sense), but he believed that the vast majority of them did not, nor was their mental capacity so interfered with that they had to abandon their business. Whether or not there was such a disease as acute melancholia was of the greatest importance because it carried with it the matter of prognosis. The outlook of manic-depressive insanity and involution melancholia had been fairly well determined, and the diagnosis of either one carried with it a serious prognosis. Dr. Collins said he agreed entirely with Dr. Dana, excepting to his statement that there were two types of melancholia with three names for them. There were three types of melancholia, namely, the acute, the manic-depressive and involution melancholia. So far as the manic-depressive type was concerned, the speaker said he knew of no disease with more clearly drawn clinical features, none which could be more readily recognized, and none in which the etiology, course and eventuation was more certain. He saw no more reason for eliminating manic-depressive insanity than he did for eliminating appendicitis, streptococcus meningitis or other well recognized conditions. As to the relation of toxic conditions to melancholia, Dr. Collins said he had never seen a case of melancholia that was relieved in any way by medication directed toward the supposed toxic agent, and the very fact that the symptoms became

intermittent or were held in abeyance by the administration of other poisons, or by an intercurrent attack of grippe or pneumonia would seem to militate against the contention that they were of toxic origin. Otherwise it would be a strong argument in favor of the doctrine of *similia similibus curantur*.

Dr. B. Sachs said that in a discussion of the classification of the melancholias, there was danger of going to extremes in both directions, and making the classification either too wide or too narrow. Under the influence of Krafft-Ebing and the older French and German writers the term melancholia was much abused. It should be restricted, he thought, to those cases in which there was a slowing up of all mental processes, associated, perhaps, with some self-accusation. This formed a very definite clinical picture, and he saw no reason why it should be eliminated. On the other hand, there were various forms of depression which could be differentiated from melancholia. In private practice he frequently made the diagnosis of simple depression; this he regarded as a transitory condition, and it had never occurred to him to look upon it as true melancholia, which was a true and very often a serious psychosis. To his mind, pure melancholia had always represented a typical and grave disorder. The question arose whether to discard the older classification entirely in favor of the more recent one of Kräpelin, with its comprehensive term of manic-depressive insanity, which included all types of melancholia, circular insanity, and what not. In picturing manic-depressive insanity, Kräpelin had shown great genius and insight, and Dr. Sachs said he indorsed that writer's wisdom in putting before the medical public the existence of a large group of cases that were characterized by typical symptoms. There could be no doubt about the existence of such a group, but he could not agree with the dictum of Kräpelin that all cases of melancholia were merely one stage of manic-depressive insanity.

Dr. A. R. Diefendorf, of Middletown, Conn., said he was surprised by the difference of opinion regarding the melancholias, as expressed by the neurologists and those who saw these cases in asylums, as it was certain that all the cases that eventually came to the hospitals for the insane had passed through the hands of the practitioner and specialist. As regards simple melancholia, there were several groups of those cases. There was one group in which the characteristic symptoms were mental sluggishness, a feeling of insufficiency or inadequacy, a lack of energy, an increased sense of fatigue, a slowing of the train of thought, difficulty of comprehension, perhaps a few indefinite hallucinations and possibly a few delusions. The emotional attitude of these patients was one of simple despondency. They took an abnormal view of life. There was another type of simple melancholia that occurred early in the course of senility.

Dr. Edward D. Fisher said he would certainly agree with the view that we had to deal with a simple melancholia which was distinct from that described by Kräpelin. Kräpelin's cases were those of later life, and differed from the melancholia which he found in manic-depressive conditions. There was in the so-called melancholia not so much absolute retardation of thought as in the class of cases of the manic-depressive type. Dr. Fisher said he had seen a number of cases occurring in young persons, perhaps about the age of twenty-five years, where they simply presented a psychosis which was described as melancholia, and where the patient made a complete recovery within three weeks to six months. He could recall one case in which at least fifteen years had elapsed since such an attack and there had been no signs of a recurrence. The speaker said he was certainly in favor of retaining the term simple melancholia, and he also believed decidedly in the manic-depressive type.

Anxiety Psychosis.—Dr. L. Pierce Clark said he was not in favor of the term involution melancholia. He thought of psychosis of the climacteric or the melancholia of involution should more properly be called an anxiety phychosis, because that seemed to be the great predominating factor. In the differential diagnosis of manic-depressive insanity and involution melancholia, the one essential feature was the retardation.

Involution Melancholia or Dementia Præcox?—Dr. A. J. Rosanoff said it was well known that depression was the most common symptom encountered among the insane. He thought that all forms of mental disease, without a single exception, might present this symptom. This fact perhaps accounted for the statement of the older writers with regard to the frequent occurrence of "melancholia." At the institution with which he was connected, and probably also at all other asylums, a considerable proportion of the depressed cases admitted had to be set aside as unclassified. The majority of these cases ultimately developed one or the other of the typical syndromes, but a small group still remained which could not be classified among the well-known psychoses. This group contained about five per cent. of the total number of depressed cases admitted to the asylum. This was merely a rough estimate, but the speaker said he felt assured that it could not be far from the actual figures. It had been proposed to designate these cases as "simple melancholia." It seemed to him that a new generic term would be entirely inapplicable to an extremely heterogeneous group of psychoses, such as these. With regard to manic-depressive insanity Dr. Rosanoff said it must be remembered that many cases presented during their whole life nothing but a number of attacks of simple depression. The diagnosis was made not at all from the occurrence of mania and depressive episodes in the same individual, but chiefly from the exceedingly well-defined symptomatology. He thought that Kräpelin had selected this term for the disease for the purpose of indicating simply that its manifestations might be either depression with retardation and dearth of ideas, or elation with restlessness and flight of ideas, or a mixture of these phenomena, but not that each individual case must present all the possible manic-depressive episodes. Some of the depressed cases of this disease were so mild that the patients were not committed, and were even able to continue their occupation; but even those cases presented the characteristic features of the disease, and one experienced in making the diagnosis of manic-depressive insanity would not have much difficulty in recognizing them. The occurrence of melancholia with anxiety and agitation at a comparatively early age had been referred to. The resemblance between these cases and those of involution melancholia of Kräpelin was only a superficial one. The speaker thought that probably almost all of them belonged to the dementia præcox group. On analysis their depression was found to be extremely shallow, it being at times but a simulated depression. Moreover, they presented mannerisms, stereotypy, neologisms, negativisms, emotional deterioration and

delusions of an exceedingly absurd or even impossible nature, contrasting with perfect orientation, intact memory for recent and remote occurrences, and a surprising alertness with regard to their surroundings.

Dr. Dana, in closing, said that on the whole, the position he had assumed in his paper had been largely sustained by those who had taken part in the discussion. He still insisted that there are two forms of melancholia, with a third that belonged more or less to one or the other. The two were the involution type and the manic-depressive. Outside of these, there were many cases of simple depression which he had learned from experience would never be anything else but simple depression, but which, if closely analyzed, would be found to belong to either the manic-depressive or the involution type. In his paper, the speaker said, he had confined himself to the functional types of melancholia, disregarding the group of simple symptomatic melancholias occurring in the course of organic brain disease. The classification devised by Dr. Parsons was very practical and interesting, especially for those working in institutions, but of course it was not intended at a text-book guide of melancholia.

A Case of Bilateral Facial Hemiatrophy.—This was presented by Dr. Edward D. Fisher. The patient was a young girl who about two years ago had an attack of persistent vomiting. Following this, progressive wasting of both sides of the face was noticed. There seemed to be no atrophy of the bone, but absolute loss of subcutaneous tissue. There were no sensory disturbances, no electrical changes.

Dr. B. Sachs said the case was unique, so far as his experience and reading went. It differed from the ordinary facial hemiatrophy in the wide distribution of the lesion, and the absolute disappearance of the subcutaneous fat without involvement of any of the other tissues. It was certainly not a scleroderma. The girl's body was apparently well nourished.

The Nature of the Nerve Lesion in Brachial Birth Palsy (Erb's Type).—Dr. Thomas P. Prout read a paper on this subject. He stated that the sequence of events in the production of the obstetrical birth palsies may be summarized as follows: The lesions are (1) immediate and (2) remote. The immediate lesion consists in a tearing of the perineural sheath surrounding and supporting the nerve trunk, and the incidental rupture of the blood-vessels belonging to it. Hemorrhage occurs into and beneath the perineural sheath. There is, furthermore, a severence of the nerve strands more or less complete, depending on the severity of the case. The remote lesion is brought about and its extent determined by (*a*) the healing of the perineural sheath; (*b*) the organization of the blood-clot; (*c*) the ultimate contraction of the cicatrix upon the nerve strands, which not only prevent their regeneration but determine a pressure neuritis in those not severed upon which it may chance to impinge. This factor is of very great clinical importance. An infant in which this accident had occurred, who remains more or less continuously peevish and fretful for some time afterward, and in whom the handling of the extremity greatly increases its pain and irritability, is suffering from a traumatic neuritis due to pressure upon certain nerve-strands of the organizing blood-clot and the contraction of the cicatrix in the perineural sheath. Cases that do not present this symptom have been produced by simple trauma to the nerve, without rupture of the perineural sheath, and will recover spontaneously, while in those cases presenting this sign of neuritis, a considerable palsy will follow, depending on the severity of the lesion. These facts have an important bearing on treatment.

Dr. Sachs said that a certain number of brachial birth palsies of the Erb type were due to pressure and nothing else. A large proportion of the cases were absolutely painless; there was simply numbness, but no pain, and no symptoms such as we could associate with a laceration of the nerve. The speaker thought that Dr. Prout took an extreme position in claiming that some of these cases, at least, were not due to pressure, and that laceration of the nerve was necessarily the cause of this type of birth palsy. There was no doubt that in some of the violent cases the nerve strands were torn, but in the large proportion of cases he thought the symptoms were the direct result of pressure and hemorrhage.

Dr. L. Pierce Clark thought from the data which he and Dr. Prout had at their command, that in the vast majority of instances the palsy was the result of stretching and laceration, and not of pressure. This was clearly demonstrated in the operative cases. In these, the recovery of the patient was uneventful, and the progress very satisfactory. The pathological work was particularly interesting, insofar as nothing like it had ever been done in connection with this type of palsy.

Dr. William M. Leszynsky said he understood from the paper that in those cases that did not undergo spontaneous recovery, surgical interference was necessary. That being the case, he assumed that Dr. Prout concluded that in all cases that recovered without operation, spontaneous regeneration of the nerve had taken place, and that those cases, therefore, had no lesion of the kind he described. The question therefore arose, when these cases should be operated upon and how could one know whether spontaneous regeneration would take place or not.

Dr. Prout, in closing, said that if spontaneous regeneration occurred, it was not necessary to operate. This could be fairly definitely known within a year or eighteen months after the birth of the child. The cases that did not recover spontaneously presented exactly the lesions he had demonstrated, which represented a condition in the perineural sheath of the nerve that prevented spontaneous recovery. It was well known that many cases recovered spontaneously, but those that did not were due to stretching and not to pressure. Those due to the latter cause would in all probability recover spontaneously. If they did not, however, pure pressure palsy was not dealt with.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

The Ninety-ninth Annual Meeting, held October 24, 1904.

The President, Wendell C. Phillips, M.D., in the Chair.

The proceedings began with reports of the various committees. The interesting features of these reports were the increase in membership as announced by the Comita Minora, and the improvement in the service of milk to New York City as the result of suggestions from the Milk Commission. There are now twenty-one farms that submit to regular inspection, and all together some five thousand quarts of the milk furnished to New York daily is obtained

under conditions entirely approved of by the Commission. Three other farms with a daily output of 1,200 quarts are getting themselves in readiness to submit to the Commission's regulations. There seems no doubt that before long only milk from regularly inspected sources will find a ready sale in New York.

Report of the Counsel of the Society.—Mr. Champe S. Andrews, the counsel for the Society, reported recent improvements with regard to the judicial view as to what constituted the practice of medicine in New York State. So far the medical law has threatened to be ineffective because of the absence of a wide enough definition of what constituted the practice of medicine. Recently a conviction before the Court of Special Sessions of a man who did not give drugs, but who insisted that "magnetism oozed from every pore of his body," and that this was the curative agent by which his patients secured health, has afforded the foundation for a precedent. The attention of the District Attorney's office was called to this decision, and as a consequence, it seems not unlikely that an authoritative definition along the same lines will be obtained from a higher court.

Number of Quacks.—Mr. Andrews said that there was a very large number of quacks in New York, and that only a few of them can be reached, mainly because of lack of funds on the part of the Medical Society. Recently the announcement that there were many thousand quacks in New York caused sensational headlines in the newspapers. To reporters who came inquiring as to the truth of this statement, Mr. Andrews said that if the New York newspapers would refuse to take the advertisements of quacks, and especially of abortionists, there would soon be fewer of them. It is the fact that they can so readily gain publicity through the columns of a supposedly respectable paper, that enables these people to carry on their nefarious business successfully. Mr. Andrews looks for the time very soon when special appropriation will be allowed for the purpose of securing the conviction of those who violate the medical laws. They are made for the protection of the community against those who have abused the confidence of the poor and the unwitting. The enforcement of the laws should be a matter of public policy and not be committed to the private exertions of a medical society.

Recent Pathological Advances.—The scientific business of the evening consisted of a series of short addresses, especially with regard to recent progress in various departments of medicine and surgery. Dr. Frederick E. Sondern spoke of recent developments in clinical pathology. He said that chemical pathology is progressing v ry rapidly, but unfortunately the amount of time required for the pursuance of any chemical examination, and the fact that any interruption of it is likely to spoil it, necessarily makes it almost impossible for the general medical practitioner to take it up. It can only succeed then in the hands of young physicians, or chemists who are not clinicians. This is, of course, an unfortunate state of affairs. Simplification of chemical methods, however, is undoubtedly common. It is very clear now that the neglect of the laboratory is as bad in the diagnosis of the disease as its exclusive use for diagnostic purposes.

Blood Pathology.—An improvement in the methods of examination for the coloring matter of the blood is sadly needed. Present methods are crude and inexact. This will evidently come along the line of examination of the absent amount of the hemoglobin and iron present in a given quantity of blood. It is leucemia particularly that blood pathology is developing. There seems no doubt now that besides acute lymphatic leucemia, which is coming to be well understood because of the number of cases observed, there is a true myeloid leucemia, that is an excess of white blood corpuscles, due to superactivity of the bone matter. Recent medical literature contains a number of existing cases of this kind.

Widal Reaction.—Dr. Sondern called attention to the fact that recent investigations seemed to make it clear that the presence of urotropin in the circulation gives rise to the Widal reaction even in persons who have never suffered from typhoid fever and who had no febrile condition at the time of its administration. Some recent experience in Japan with personal observations, shows how much better the Japanese use all the precautions necessary to procure an exact Widal reaction than is the custom in supposedly much more advanced countries. The amount of culture and of blood is taken very accurately, and the dilutions made according to very exact methods in Japan. It is only in this way that the Widal reaction can always be depended on. Dr. Sondern called attention to the fact that an increase in the number of leucocytes in infected cases is as yet of questionable value in regard to pus formation and the prognosis of the case. Careful differential leucocyte counts give much more satisfactory answers, than the mere number of leucocytes in general. Cytodiagnosis seems also to be gaining a foothold for itself as a diagnostic method. Dr. Sondern considers that present methods of diagnosis in examination of the urines are crude and apt to be indeterminate. It is probable that the amount of urea excreted in any one day or at any time, has no special significance unless the amount of material ingested by the patient is known. The present system of noting of history sheets in hospital wards, the number of grains of urea per ounce of urine does not give as much information as if the total amount of urea passed per day were always known. Owing to the uniformity of diet in hospital service, this would usually give some definite information as to metabolic processes and the course of excretion.

Antistreptococcic Serum.—Dr. William H. Parks said that Professor Escherich, of Gräz, has recently treated a series of scarlet fever cases by large doses of antistreptococcic serum, using as high as 150 c.c. of serum for a patient with reported good results. There was a time not so long since when the streptococcus was thought to be the probable cause of scarlet fever. Since the description of Mallory's bodies in scarlet fever, there has been a general tendency to consider that they probably represented the cause of the disease, and were very likely protozoic in nature. They certainly occur in all cases of scarlet fever, and may be found abundantly in the fluid obtained by blistering a scarlet fever patient. It is probable, therefore, that what Escherich really does is to prevent secondary complications in scarlatina, for it is well known that the streptococcus is likely to cause secondary infection in these cases.

Summer Diarrheas.—Studies made during the last year show that the summer diarrheas of children in our large cities in this country are not due to the dysentery bacillus, as was thought for a time, nor to any of the types of the Shiga bacillus. In fact, so far, it seems clear that acid bacilli are not concerned in the etiology of the disease. Some of the acid bacilli are found in normal individuals, while in some

cases of dysentery they do not occur. As would readily be concluded from this, dysenteric serum does no good in the treatment of the disease.

Diagnosis of Rabies.—Dr. William H. Park said that the diagnosis of rabies has apparently been very much simplified by the discovery that certain bodies resembling protozoa can be found constantly present in the nerve tissues of sufferers from the disease. They may be demonstrated even in a smear of the brain of an affected dog. They do not occur in normal animals. This would simplify very much one of the most serious problems in bacteriological diagnosis. Some discoveries are apparently about to be made with regard to tetanus. The question of injecting antitoxin into the sheaths of the nerves has been seriously discussed, and even tried in some reported cases. That some such method of injection was necessary has long been known and has recently been still further demonstrated by the observation that adrenalin will neutralize tetanus antitoxin, though it does not modify in any way tetanus toxin If the antitoxin is put directly into the circulation, it is sure to meet adrenalin in sufficient quantities to neutralize it very materially while the toxin continued to spread upward through the nerve, unaffected practically by the slight amount of antitoxin that may reach it if the injections are made in the ordinary way.

Water Purification.—The most interesting thing with regard to the improvement of the water supply of cities is the introduction of copper sulphate as an agent for the destruction of algæ. As is well known, this substance is a disinfectant, and will kill ordinary bacteria in twenty-four hours even in a dilution of one to 400,000. As in this dilution it is absolutely harmless, it would seem to be a valuable agent. It kills the algæ very rapidly in badly affected water, and especially gets rid of the fishy smell and taste, which has been so obnoxious in certain waters in which algæ grow luxuriantly.

Some Fads in Surgery.—Dr. Howard Lilienthal said it has been suggested that the word "fad" is due to the use of the three initial letters of the words "for a day," which so well represents the essence of the fad. It is defined by the Century Dictionary as a trivial matter, or as an important matter followed up with more zeal than sense. Medicine and surgery, of course, are sure to be fertile fields for fads. It is easy, however, to suspect really excellent modification of current practice as being fads. In surgery, here in America, the last twenty years have seen many unfortunate fads. Oophorectomy was supremely overdone, and though now this special organ is not so much abused, hysterectomy is as yet a fad for certain gynecologists. At the present moment the gynecological fad, however, is the rivalry to see which surgeon can remove the largest fibroma per vaginam. One is reminded of the expression of the old negro woman who said to the young woman going to the hospital, "Don't you let them cut your stomach. You go to Dr. So-and-So. He'll take out your tumor through the pajama."

Movable Kidney.—The supreme field for fads at the present moment is the movable kidney. Some surgeons cannot palpate a movable organ without wishing to anchor it. Slight amounts of mobility of the right kidney are so common in women that there might be serious question whether a fixed organ on this side were not more abnormal than a movable one. Mobility should certainly not be the only reason for wishing to operate on a movable kidney. So long, however, as it continues to be so remunerative, the fad will probably continue. All sorts of symptoms are traced to a movable kidney. Dr. Lilienthal has recently seen a gastric carcinoma, in which an operation for a movable kidney had been done within a year before death. As regards operations for Bright's disease, theory has always been against them, except in such acute cases as those operated upon by Reginald Harrison and now practiced, is also against them.

Radiotherapy.—There seems no doubt that radium will prove of great service in the treatment of malignant growths. Where such tumors are deeper than the skin, however, no one would think of using any form of radiotherapy until after the knife has been employed if the cases are operable. After extirpation as far as possible, then radiotherapy may be employed to assure a cure. There is no doubt, however, that in some cases these methods of treatment seem to stimulate malignancy. The newer things in surgery have a definite place, but it is only after old, well-tried and established methods are proven unavailing. To run after every new notion is to expose oneself, not only to serious error, involving life in the case of serious surgical operations, but also keeping the surgeon from proper-rounded development of his surgical skill. The poet's old rule still remains the best advice in this matter:

> "Be not the first to lay the old aside,
> Nor yet the last by whom the new is tried."

Business Methods in the Practice of Medicine.—Dr. John S. Thatcher said the reason for success in medicine is not always easy to decide. It is not always a man of the most brilliant attainments who succeeds the best, nor is it the man always of most go-ahead qualities who makes an eventual success. Energy and straightforwardness seem to be the main elements for the practice of medicine. Genius seems to be scarcely more than an infinite capacity for taking pains. A charming manner is sometimes said to be the secret of success. It has its uses, but it must be combined with other qualities. It is not the most affable plumber that you send for again, nor the most courteous carpenter who gets all your work. Some physicians delay the hour of their visits on the pretense of being so busy, but a prompt business-like method will be better. Directness and thoroughness are qualities that must be cultivated. The story is told of an old physician who, in a hurry one morning, advised the young man who called on him to take a prescription that he gave him and felt sure he would be better, but when the young man said, as he was about to leave, that he was the son of an old friend, the physician said, "For Heaven's sake, throw away that prescription, and let me look you over!" There is an unfortunate fear of the possible evil results of telling the truth to patients that has gone entirely too far. For the patient, it is often better to know the worst. Even in hopeless cases, he rises more manfully to the emergency than when he fears the worst and thinks that it is being kept back from him. For the family, knowledge of the truth is better than the fearful uncertainty when it is known that patients are seriously ill. Of course, there are those who say that the physician should tell the truth, but in small quantities. There is a growing doubt, however, of the advantage of this policy. Unfortunately, physicians are not able to accomplish as much as they would like to. As Alonzo Clark once said, "Disease may be cured, but death is inevitable."

Postgraduate Medical Instruction.—Dr. D. B. St. John Roosa said that New York City originated and organized postgraduate medical instruction in the English-speaking countries. In England, notwithstanding well-directed efforts in recent years, postgraduate medical instruction has been a conspicuous failure. This is especially true of London. Everyone who has been in the English capital knows what limited opportunities for postgraduate instruction are going to waste there. Nearly the same thing is true of Edinburgh. Notwithstanding what might be accomplished in their great infirmary, the Scots have not succeeded in organizing postgraduate instruction. Paris is without a system that encourages physicians to come for instruction, and there is no hospitality, so that medical visitors looking for opportunities are almost driven away. In general, it may be said that the work is not appreciated in France.

New York Postgraduate Medicine.—As the result of proper organization in this city from 750 to 1,000 physicians are attracted here every year for postgraduate work. The organization of this system of instruction was successfully accomplished at a time when New York had lost some of her prestige in undergraduate instruction, and was being overshadowed by Philadelphia, if not also by Chicago. As a matter of fact, the postgraduate medical instruction movement saved the medical center for New York. At the present time, however, the system is at a standstill for need of funds. It is possible that something may be accomplished by affiliation with the regular medical schools. This affiliation was refused when the postgraduate system of instruction was initiated. There is no doubt now that the postgraduate courses have come to stay. No matter how much the increase of instruction in undergraduate courses, physicians will still feel the necessity of coming in direct contact with cases in order to fit themselves for practice, and, besides, physicians who have been out of practice for many years, will occasionally want to come back in order to set themselves *au courant* with the state of medicine at a given time. Perhaps the greatest compliment that has been paid to the New York system of postgraduate instruction is the fact that the plan adopted is now being imitated in Cologne and in Frankfort. The future of the system depends on proper recognition of its merits and a due support according to its needs.

SOCIETY OF THE ALUMNI OF CITY HOSPITAL.

114th Stated Meeting, held April 13, 1904.

Some Practical Points in Medical Diagnosis.—Dr. Morris Manges spoke extemporaneously on this subject. He considered, (1) cerebrospinal meningitis; (2) paratyphoid; (3) perforation in typhoid. He said that it was impossible to determine or even to understand these epidemics of cerebrospinal meningitis. The particular type under consideration was characterized by a sudden onset and a fulminating course. He cited two cases which had come under his observation, in one of which the mother had died and was buried.—one and a half hours later, the daughter, eighteen years of age, was comatose from the same disease. In the other case a man had gone into coma within an hour from the first symptoms. The headache of epidemic cerebrospinal meningitis, he said, is characteristic. Typhoid is apt to be frontal, whereas this is very general, and it is so severe that the patients cry out even though in coma, the pain being dreadful. Vomiting and photophobia are common. The posture is characteristic, flexion being typical with the patient lying on the side. The eyes are frequently bloodshot and the pupils irregular, face dusky and anxious. Herpes is typical of pneumonia and cerebrospinal meningitis. But the symptom is of more value in this disease than in any other for diagnostic purposes. As in typhoid, relapses are very common. The reflexes are soon diminished and König's phenomenon is always present. The eruption is variable both as to distribution and as to type. It often looks as though a rough brush had been used freely in the neighborhood of the great joint. The leucocyte count is usually high, not infrequently reaching thirty thousand. In establishing a differential, it must not be forgotten that there may be sugar in the urine, from cerebrospinal coma. Lumbar puncture is invaluable to prove the diagnosis without question, and as it has a distinct therapeutic value and does no harm, it is certainly indicative. The speaker advised the injection of a few drops of lysol directly into the spinal canal.

Paratyphoid.—The chief interest in this disorder centers in the fact that it affords an explanation of the so-called cases of short typhoid. It is characterized by the presence of the paracolon bacillus and by the absence of Widal reaction. Paratyphoid is simply not typhoid, its etiology being complex. It should therefore be called pseudotyphoid. Further differential points, which serve to distinguish it from typhoid are as follows: The facies are different. The patient appears more ill, there being a high flush over the malar bones. The spleen is apt to be larger. The rash is extremely profuse; this probably serving to explain the well-known old-fashioned belief that a free rash in typhoid is a good sign.

The classical picture of perforation is usually very untrue. The most important symptom is the question of degree and position of the pain. The pain of perforation and the normal pain of typhoid are often indistinguishable. The author considers that severe referred pain in the tip of the penis is pathognomonic of perforation. Collapse is invariably present if the perforations enlarge, and is equally sure to be absent if they are small. There is a distinct change in the general condition of the patient, although it is difficult to state the exact nature of this change. The pulse usually rises. It loses its dicrotic character. The condition of the abdomen is variable, distention being of little or no diagnostic value. What is characteristic is muscular resistance and rigidity, it being typically located over the perforation. In conclusion, he said, that in nineteen cases a sudden onset had augured favorably for the patient, simply because it had enabled surgical intervention to be practised. No one should be asked to give the positive symptoms of perforation, for if they exist, they have not yet been determined. The question of surgical intervention should be left open much as in the case of appendicitis. Probably 90 per cent of cases of perforation do not die, for in all probability a great many perforate which are never recognized. There is but one treatment, namely, operative, and that should be instituted even if there is only a suspicion of perforation.

Wood's Footsore Moros.—Gen. Wood says that the native constabulary paid by the United States are crippled by shoes, lose their stamina by wearing "civilized" clothes and are made fat and short-winded by an unaccustomed diet. The history of colonization is full of tragic instances of the evil effects of interference with the ways of primitive races.

BOOK REVIEWS.

A Treatise on Obstetrics. For students and practitioners. By Edward P. Davis, A.M., M.D., Professor of Obstetrics in the Jefferson Medical College, Philadelphia, etc. Second Edition. Illustrated with 274 engravings and 39 plates in colors and monochrome. Lea Brothers & Company, New York and Philadelphia.

It is a pleasure to find an obstetrical text-book which does not begin with a description of the mons veneris and devote the first hundred pages to an anatomical description of the female generative tract. The writer appropriately considers the subject of obstetrics a senior study, and assumes that the student shall have become familiar with ovulation, menstruation, impregnation and the anatomy of the pelvis from other sources. The work is strictly an obstetrical treatise, possessing most commendable radical changes in the arrangement and presentation of the subjects. Much of the old nomenclature has been dropped and the mechanism of labor, fetal presentation and position has been simplified.

The author adopts the German plan of considering but two fetal positions. Cases in which the back of the child is directed to the mother's left are called first positions. Those in which the back of the child is toward the mother's right are called second positions. Cases in which the presenting part is not in front are considered instances of defective rotation rather than separate positions. A permanent and most excellent section of the book is the part devoted to the surgery of pregnancy, labor, and the puerperal state. Realizing how much suffering may be avoided by prompt repair of injuries received during labor, careful attention has been paid to the description of proper surgical procedures.

The chapter on milk modification and artificial feeding is brief and incomplete, the writer evidently intending that the reader shall acquire knowledge of other than the fundamental principles of the subject from other sources. A chapter is devoted to a brief description of the more common diseases of infancy, a convenient section for hasty reference or review.

The last section on the Jurisprudence of Obstetrics affords interesting and profitable reading.

This second edition has been thoroughly revised, is well-illustrated, well printed, neatly bound and is without question one of the best books on the subject that has yet been published.

Manual of Serum Diagnosis. By Dr. O. Rostoski, University of Würzburg. Authorized Translation by Dr. Charles Bolduan. First Edition. John Wiley & Sons, New York. Chapman & Hall, London.

This book is in part a translation, in part an amplification of Rostoski's short treatise on serum diagnosis, published in the *Würzburger Abhandlungen*, in 1903. The material on which the original German work was based has since that time become considerably more voluminous, and Dr. Bolduan has therefore, very judiciously added many important details upon serum diagnosis. There is also an important appendix embodying Wilson's conclusions on the Gruber-Widal reaction. The volume is, therefore, a reliable and thoroughly modern treatise on serum diagnosis and allied topics, both from the theoretical and the practical standpoint. The student of these phenomena can learn the essentials of serodiagnosis, as far as they have been elaborated in typhoid, tuberculosis, scarlatina, etc., in this little volume. For a complete or profound analysis of the problem, however, he will have to consult the larger works and the original authorities.

Accidents and Emergencies. A manual of the Treatment of Surgical and Medical Emergencies in the Absence of a Physician. By Charles W. Dulles, M.D., Fellow of the College of Physicians, of Philadelphia, and of the Academy of Surgery; Surgeon to the Rush Hospital, etc. Sixth Edition, revised and enlarged with new illustrations. P. Blakiston's Son & Co., Philadelphia.

The appearance of this latest edition of a charming and well-known little book is welcomed by all. The present volume has been carefully revised, many illustrations and much new matter having been specially prepared for it. Particular attention has been given to the notes on accidents arising from contact with powerful electrical currents, good common-sense instruction being given in the very important method of how to remove a person who has been caught in such a current. A very important chapter is that which deals with the transportation of injured persons. The photographic illustrations of the methods employed are particularly serviceable to all readers.

A striking feature of this little book is its remarkable versatility, the chapter on the treatment of poisons and on poisonous plants being particularly significant in this respect.

Blood Pressure, as affecting Heart, Brain, Kidneys and General Circulation. A practical consideration of Theory and Treatment, by Louis Faugeres Bishop, A.M., M.D., Physician to the Lincoln Hospital, New York City. E. B. Treat & Co., New York, 1904.

Too little is as yet definitely and finally known as regards blood pressure for a monograph with regard to it to be other than theoretic. Dr. Bishop's book is mainly concerned with the theory of the subject, though it also contains the details of some observations on medical patients with the Riva Rocci Sphygmomanometer and some really suggestive hints as to the treatment of patients in whom high arterial tension is a main feature.

Clinical Lectures on Mental Diseases. By T. S. Clouston, M.D., Physician Superintendent of the Royal Edinburgh Asylum for the Insane. Sixth Edition. Lea Brothers & Company, New York and Philadelphia.

It is always a mental enjoyment to find a book that has gone through five editions, extending over a number of years that has been able to keep its old moorings because of their soundness and yet find it laden with much of the newer fruits of research.

It can be consistently said of Clouston that the body of his work remains the same because it was so excellently done in the first place. No one has exceeded him in the clearness and directness of his clinical pictures.

In modern psychiatry two distinct trends are observable among the many streams of new thought—the pathological and the psychological. Modern psychiatric pathology is being attached by the same methods of research as general pathological questions, much to the advantage of psychiatry. In this line Dr. Clouston has been able to keep his work well advanced, although at times he permits the "auto-intoxicationists" about him to sweep him away from these same general pathological truths.

The newer psychology, however, is not as well revealed in this present instance as we should like to see. In this respect we believe that Clouston lays behind the modern treatises of Lichen, of Wernicke, Kräpelin, Tanzi and others. Nevertheless, for students or non-psychologically trained practitioners we know of few safer books to recommend than this.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 85. NEW YORK, SATURDAY, DECEMBER 31, 1904. NO. 27.

ORIGINAL ARTICLES.

THE EFFECT OF HYSTERECTOMY ON THE SEXUAL FUNCTION.[1]

BY HIRAM N. VINEBERG, M.D.,

OF NEW YORK;

ATTENDING ADJUNCT GYNECOLOGIST TO MT. SINAI HOSPITAL; VISITING GYNECOLOGIST, ST. MARK'S HOSPITAL, ETC.

IT was with some reluctance that I responded to the invitation of the Chairman of the Obstetrics Section to write a paper on the subject. I fully appreciated the honor implied by the invitation, but had a strong sense of my inability, with the time at my disposal, to present the subject in a manner worthy of this body.

The whole question of sexual passion in women is surrounded with great vagueness, and it is not possible to make any definite statements regarding it.

Women, especially those in this country, are very loath to discuss matters relating to their sexual feeling, and what statements they do make in reference to it cannot always be accepted without reserve. Hence it is that I seldom interrogate my patients on that point, and further I have learned from experience that if they are really devoid of any sexual desire or pleasure they will of themselves volunteer the statement. A still further reason for my not investigating the presence or absence of the passion is that in my opinion it has very little bearing, as a rule, upon the conditions for which the patient seeks advice.

In sterility, where it is popularly held that the absence of sexual desire forms an important etiological factor, I have long ago learned that it plays absolutely no rôle. Some of the most fruitful women that I know, women with large families, are totally devoid of any sexual appetite. On the other hand, I know women with small, undeveloped uteri, in whom conception is a physical impossibility, and yet who have the sexual passion developed to a high degree.

This leads us to the question of the seat of the sexual passion in the human female.

Albert Moll,[2] who has written an exhaustive and scientific treatise upon the subject, divides the sexual instinct of the human adult into two components, (1) the detumescence instinct is that which forces to a local function of the genitals, and in man to an ejaculation of semen. It is to be considered as a purely local process, an organic stress to the discharge of a secretion, just as is the desire to urinate when the bladder is full. (2) The contrectation instinct is that which forces the man to a bodily and to a spiritual approach to the woman, and similarly the woman to the man.

Phylogenetically the detumescence is the primary means of procreation, being the only instinct present when procreation is accomplished by one parent, as in some plants and lower animal life.

The contrectation instinct is only a secondary manifestation, when a stage is reached in evolution that requires two individuals for procreation.

In women, in the evolution of the stock, the detumescence has become separated from the function of the generative glands (the ovaries), although originally both processes were united.

The detumescence instinct has its center in the lumbar portion of the spinal cord; the contrectation instinct has its center in the cerebrum.

Accepting Moll's definition as correct, we can readily understand why the sexual passion is less strong in woman than in man, an observation that has been made by several authorities. It also explains why, in woman, the individual plays a much greater factor than in man. We all know that with man it is often "any port in a storm," but when a woman betrays such a tendency we look upon it as a morbid condition known as "nymphomania."

We find in it a further explanation of the phenomenon, not infrequently observed in women, of a strong desire to be fondled and embraced, which may even be associated with an overpowering repugnance to the sexual act itself. Time and again I have had husbands tell me that the sexual act to their wives was repulsive to a degree, although kissing and tender embraces were not only enjoyed by them, but seemed to be a passion with them.

From what has gone before we are prepared for the statement, which otherwise might seem rather startling, that the removal of the uterus and adnexa from an adult woman has very little effect upon her sexual passion.

This statement is based upon the writer's own recent investigation and from a perusal of the reports of several operators. I am perfectly aware that the opposite has been the popular belief, and I will grant that the belief has some foundation. Until about two decades ago the only knowledge we had of the effect of the removal of the ovaries from the human female was based upon the facts related by travelers from countries where it was the custom to castrate girls before the age of puberty.

For instance, Ploss, in his wonderful work, entitled "Das Weib," quotes Roberts who relates in his travels from Delhi to Bombay of having seen a girl from whom the ovaries had been extir-

1 Read at a stated meeting of the Academy of Medicine as part of a symposium upon the After-Effects of Hysterectomy, Oct. 6, 1904.

2 Untersuchungen über die Libido Sexualis, H. Kornfeld, Berlin, 1898.

pated. The girl had no breasts, nor any hairs nor fat on the mons veneris. She had considerable hair on her chin and upper lip, and had a decided masculine appearance. She was utterly devoid of any sexual desire. Travelers in Queensland describe similar instances of removal of the ovaries before puberty with the same after-effects. It is no doubt from remembering such tales that at the present day the operator is occasionally met with the tearful query, "Doctor, if you remove my ovaries will hair grow on my face, and will my disposition change and will I become masculine?" I will not say that the belief has not found some foundation even in modern days when in the early days of gynecological abdominal surgery it was the custom to remove practically normal ovaries from fairly young girls for all kinds of nervous ailments. I am glad that it fell to my lot to become active in gynecological surgery when that wave of blind enthusiasm had entirely receded. My own experience therefore relates to cases in which hysterectomy was done for marked disease of the adnexa or for disease of the uterus, such as benign and malignant growths.

Since learning of the part I was to take in the discussion to-night I wrote to several of my patients, of the more intelligent class, whose uteri and adnexa I had removed for disease. The invariable reply was that the operation had had no effect upon their sexual passion one way or the other. Prior to this investigation, in a few instances, patients had volunteered the statement to me that they never knew what sexual pleasure was until after the operation had been performed. In a few other instances women had told me that the sexual appetite had increased in a marked degree subsequent to the operation. I can recall no instance where a woman had told me that the operation had destroyed her sexual desire or pleasure. In all of the above instances the operation was done for very advanced disease on both sides, with extensive adhesions to the pelvic floor. We can readily conceive that in such conditions the sexual act would be attended with more or less pain, and in consequence a feeling of fear or repulsion would be engendered.

Drs. Mandl and Bürger,[1] of Vienna, have recently written an exhaustive monograph on the subject of the effects following the removal of the uterus and ovaries. The effect of the operation upon the sexual passion is given by them with that fulness of detail which could only be obtained from a *clientele* who are not ashamed to discuss the sexual feelings with openness and candor. They investigated the subject in 22 women. In seven cases there was absolutely no change in the sexual passion. In nine cases there was a decrease, and in the remaining six cases there had been no sexual intercourse following the operation. Of the nine women who said there was a decrease, several were rather advanced in years and would naturally experience a diminution of the passion.

The conclusion I would draw from my own experience and from a study of the literature on the subject is that whatever other effects the removal of the uterus and ovaries may have upon the female human economy, it has little or none upon her sexual feelings.

THE DIFFICULTIES OF ANESTHETIZATION AND THEIR CORRECTION.[1]

BY VICTOR C. PEDERSEN, A.M., M.D.,

OF NEW YORK;

ANESTHETIST AND INSTRUCTOR IN ANESTHESIA AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL AND ANESTHETIST TO THE ROOSEVELT HOSPITAL.

The difficulties of anesthetization necessarily comprise those arising during administration and those arising during convalescence. These two classes will be considered in the order in which they occur. The fright and misunderstanding which are at the basis of hesitating, imperfect or suspended respiration during the early stages of narcosis may be alleviated by suitable reassurance and explanation. Deliberation and care in administration will likewise correct the reflex irritation so frequently an element therein. These difficulties may arise during nitrous oxide administration and then indicate admission of air. Crying, frequently seen in children, occasionally in adults, is entirely trivial excepting during chloroformization in children, when the long inspiratory stage so frequently observed may lead to overdose. The falling back of the tongue may excite persistent hesitation of respiration even after the early stages and is best corrected by a mouth gag of moderate size and the use of tongue forceps. Muscular movements give evidence of excitement; and muscular rigidity, of an obscure nervous reaction which may be exceedingly inconvenient, especially when it attacks the masseters. Rigidity is most apt to be localized in all the extensors, and no subject is suitably narcotized until this rigidity is absent, a condition which occurs, as a rule, after the judicious increase of the drug used, although occasionally advent of air will secure it. The movements may be conscious, subconscious and unconscious, and are frequently well coordinated although not necessarily directed against the anesthetist or the apparatus. The gentlest possible restraint to overcome them is indicated, as violence is more apt to increase than to diminish them. Tonic movement analagous to the tonic spasm of asphyxia indicates fresh air or a change from ether to chloroform or *vice versa*. Clonic movement is very common, usually located in the lower extremities but rarely generalized. Brewer has reported a case in which the patient nearly shook himself from the operating table no matter what anesthetic or combination of anesthetics was employed. These muscular movements usually indicate imperfect administration, hysteria, drug habit and perhaps most commonly of all, a premature invasion of the operative field, especially if

1 Read before the Society of the Alumni of the City (Charity) Hospital, October 12, 1904.

sensitive. Cough occurs during slight anesthesia after additional drug has been applied. It is founded most frequently on a long uvula and the adenoid diathesis and what might be called the tobacco throat. It is treated by removal of the anesthetic until the individual spasm ceases and then by a gradual increase in the anesthesia or a change to another anesthetic. Here again if chloroform is used care should be exercised not to overdose during the deep inspiration after the cough. Hiccough, while of minor importance to the anesthetist, may trouble the operator through the spasmodic action of the diaphragm and abdominal parietes. It is most frequently set up by manipulation of the intestines and gall-bladder. If marked, treatment is of little avail although a brief cessation of operating followed by a deepening of the narcosis may check it.

Stertor is, far more than most operators fancy, purely a matter of valve-action between the soft palate, pharynx and tongue, being in these circumstances entirely analagous to snoring. If the mouth is held open and the tongue forward it is possible to carry a very large number of patients through etherization as quietly and as stertor-free as during chloroformization. Stertor may also be caused by mucus in the throat, being in this analagous to bronchorrhea. The prophylaxis of bronchorrhea consists in care in administration. The cure of it frequently occurs after a single large dose of atropine. The mucus should then be wiped away from the throat or drained away with gauze.

Retching and vomiting are not only difficulties but dangers because they interfere with the operator, may readily cause inhalation pneumonia and be directly followed by death, especially with chloroform. The best correction of them is to free the mouth of instruments, to allow the paroxysm to pass and then to deepen the narcosis rather rapidly and steadily. The most important single cause is intestinal obstruction during which regurgitation often without esophageal movement occurs. Rose's position is the safest for these individuals, because the stomach contents may rest in the vault of the pharynx while being wiped away without interfering with breathing. The nose also in this position frequently will allow the vomitus to flow out while the patient breathes through the mouth. Hewitt recommends turning the patient slightly upon the side so that a similar reservoir is obtained in the lateral regions of the nasopharynx. Sneezing may occur as a minor difficulty dependent upon a chronic hypertrophic nasal catarrh. Cocainization is the indication.

We now pass to the major difficulties, properly the dangers, of anesthetization. Respiration may be occluded by altered position, spasm, swelling of the parts within or around the upper air passages, such as falling of the lips together in the edentulous, apposition of the turgescent tongue, soft palate and pharyngeal wall, and spasm of the jaw, larynx or chest. Each condition carries with it self-evident indication. The swelling of the mouth contents is the most common. The average case does better with mouth gag and tongue forceps than without. Adventitious substances, too numerous to mention, may likewise obstruct breathing. The most common are blood, vomitus, mucus, tooth plates and the like. Removal of the offender is required, but tracheotomy may be the only means of rescue. For this reason it is good practice never to attend an operation as anesthetist without a full tracheotomy set. Posture may arrest breathing by direct prevention of chest expansion; for example, the prone or semi-prone position in kidney cases, in which the chest should be elevated from the table by a sandbag across the clavicular regions from shoulder to shoulder, as pointed out by me in an article upon this subject about a year ago. Morbid states like ascites, empyema, pleurisy and hydropneumothorax are also elements in obstruction of respiration. After considerable experience the writer believes that the average case of ascites, empyema or pleurisy will take the anesthetic with comparative safety, if the fluid is drawn some hours before the operation, thus removing the obstruction so far as possible. Operations upon the thorax and abdomen may cause a reflex arrest of breathing which is very difficult to deal with. The writer has never seen more than trivial cases thereof, which improved as soon as the operating was suspended. Paralysis of breathing may be wholly or partially due to overdose, almost always comes on slowly and is shown by a progressively shallower and shallower respiration, finally by irregularity and then by cessation. Sometimes the arrest is sudden as in chloroform, but is usually preceded by circulatory symptoms. Shallow breathing with good color, a strong pulse and normal pupils, which continue so is a good sign; whereas shallow breathing with pallor, cyanosis, rapid uncertain pulse, dilated fixed pupils, inefficient capillary circulation, is a sign of impending death from the anesthetic. The anesthetic should be immediately removed, and free stimulation and active artificial respiration resorted to. Hewitt suggests rubbing the lips vigorously from side to side upon the teeth as efficient means of causing deep respiration. The author has tried this on several occasions and has not been pleased with its results.

Respiration may be paralyzed by causes other than overdose of anesthetic; for example, chloroform may so lower the circulatory pressure as to produce profound cerebral anemia; similarly, changes in posture especially from the cerebral turgescence of Trendelenburg's position followed by the anemia of the horizontal position, or the horizontal followed by the sitting posture. What may be called changes in the mechanics of the circulation are exceedingly dangerous from this one source. A preliminary dose of morphine may add to the danger. Absolute inhibition of respiration may occur and is said to be common in adenoid and tonsil cases under chloroform. Such

cases must be rare where there was not some mechanical obstruction to the larynx such as by blood. Removal of this quickly restores the patient. In every such case the anesthetist should open the mouth widely and pass his finger into the cavity of the larynx to explore for the presence of offending foreign objects. Stimulation, artificial respiration and infusion will probably do the rest if there is any hope for the patient.

The circulatory dangers of anesthetization are perhaps less important than the respiratory, excepting such as are inherent in chloroform. Impairment of health in general, as seen in anemia, jaundice, nephritis, hepatic cirrhosis and grave respiratory diseases predispose to them, as do fear, the sitting posture, and food and fluid in the stomach. These circulatory dangers may be directly caused by any of the impediments of respiration previously enumerated, by the direct effect of the anesthetic as chloroform, by the surgical procedure itself, especially perhaps in the neck and the regions of the stomach, and finally by the changes of blood pressure during vomiting. The author has never seen a sudden case of cardiac failure excepting in a soldier already moribund from typhoid fever contracted in Cuba during the Spanish-American war. He was being anesthetized for a laparotomy for perforation. The medical staff requested interference; the surgical did not wish to undertake it, but yielded. The man died suddenly in the etherizing room after a few whiffs of anesthetic. In other cases circulatory difficulty was always indicated by failure of capillary efficiency. This is tested by squeezing the blood out of some convenient point and watching the promptness of its return. No points are better than the finger nails, lips and the malar regions and the lobes of the ears. The finger nails are first choice because the anesthetist may always compare his own capillary circulation with that of the patient. If there is a distinct slowness, it has been the writer's practice to stimulate and never has regretted following this indication. As a precursor of shock it appears before the nose is cold or the skin even slightly moist with perspiration. It appears before one could be certain of changes in the quality of the radial or temporal pulse. It usually precedes even acceleration of the pulse and taking all in all in the *sine qua non* of circulatory tests.

Cyanosis may have its origin in respiratory or in circulatory factors. When due to respiratory conditions it may arise from absence of air, laryngeal spasm, concentration of vapor, direct obstruction of the upper air passages, interference with respiratory movements of the chest through factors in the chest or in the abdomen, like empyema, edema of the lungs and ascites. The correction of these conditions has already been enumerated under other headings, and need not be repeated excepting, perhaps, the dictum that the upper air passages should always be most carefully explored with the finger and when no proper cause is found auscultation of the chest must immediately be done. The writer has had the privilege of saving one subject from death from edema of the lungs by exactly this step. Circulatory cyanosis may mean, of course, imperfect aeration but usually means flagging heart. It is always accompanied by inefficient capillary circulation which constitutes the chief differential diagnostic point between pure circulatory and pure respiratory cyanosis. Free cardiac stimulation is required.

The difficulties of convalescence from anesthesia is a subject which most authors neglect. In my opinion proper care during the first twelve hours of recovery is equal in importance to skilful administration. The features of recovery may be stated as dependent upon the duration of the operation, the amount and kind of anesthetic employed and the character of the administration. For example, the average patient should be able to talk coherently in about fifteen minutes after withdrawing the anesthetic, no matter what the character or nature of the operation may be, because the skilful anesthetist will so vary the degree of anesthesia as to make this possible. On the other hand, the author knows of a case that did not recover for seven hours from the anesthetic because a veritable tyro administered nearly twenty ounces of ether in less than an hour, notwithstanding the fact that the patient was a temperate individual. Hewitt recommends that on return to bed if the pathological condition permits, the patient should be turned upon the side. The tongue then drops to that side of the mouth, the air passages open, stertor ceases, mucus and saliva gravitate out of the mouth and not backward into the throat and coughing is prevented because the tongue, soft palate and pharnyx separate and because mucus leaves the mouth of the larnyx. A competent nurse or the anesthetist should stay with the patient until distinct signs of recovery are present in order to institute restrained stimulation or other treatment as need may arise. Pallor and feebleness of pulse may show shock but will then be accompanied by cold extremities and nose and feeble capillary circulation. They are more apt to mean threatening vomiting or the result of withdrawing a stimulating anesthetic as is the case with ether. The question of nourishment during convalescence may be difficult, especially if the patient is suffering from protracted vomiting. The best treatment for the general run of cases is to allow the patient all the hot water he will drink. If inclined to vomit he has the substance present to eject which is very much less damaging nervously than dry retching and at the same time the water washes the stomach free of the ether-laden mucus. Food may be given as soon as the patient expresses real appetite for it, and should be fluid and predigested for the first twenty-four hours. Food in the stomach prior to the administration of the anesthetic, the character of the

anesthetic used, especially ether, personal idiosyncrasy, the nature of operation, particularly intestinal organization, are factors in the after-vomiting. In the protracted case perhaps the most sensible thing is lavage.

Finally, in closing, one detail should be emphasized which is very largely neglected, especially in institutions, and that is not to expose the patient so as to endanger a check of the perspiration, which is usually profuse and always present during recovery. The best recoveries occur when the patient is wrapped in several thicknesses of blanket from head to foot, leaving only the face exposed and thus constituting a veritable hot pack. When the patient is fully conscious he may be uncovered part by part, rubbed down with a bath towel and dry clothing applied. This procedure renders congestion of the lungs unlikely and, in fact, tends to relieve congestion of the kidneys also. The writer has practised it now for two years in all cases and has yet to see the slightest objection to it.

HYPERACUTE MELANCHOLIA: REPORT OF A CASE.

BY ROBERT N. TODD, A.M., M.D.,
OF INDIANAPOLIS, IND.;
ASSISTANT PHYSICIAN, CENTRAL INDIANA HOSPITAL FOR THE INSANE.

SINCE M. Baillarger demonstrated stupor to be the highest expression of acute depressive insanity, it has generally been so considered by the French school of which Prof. Régis, of Bordeaux, is in this country regarded as the modern exponent. To this latter author we are indebted for the term "hyperacute melancholia," a condition which he declares stands in the relation to melancholia that acute delirium does to mania. He further states that "the majority of foreign authors recognize and describe under the name of attonität and of katatonia (Kahlbaum), conditions which are fundamentally, as Séglas and Chaslin have recently demonstrated, nothing else than melancholia with stupor, under its different aspects and in which predominate either the phenomena of hebetude or spasmodic and cataleptic symptoms." With this conception of the psychosis, the following is the report of our case:

Mrs. R. L., aged twenty-four years, white, married six years, has three children, age of youngest ten weeks, high school education, member of Christian Church, admitted to hospital June 26, 1903, the disease having existed 2½ months prior to admission. No history of heredity of psychosis or neurosis; assigned cause ill-health and puerperium; last confinement was on April 17, 1903; previous to this she was delusional. Patient was very melancholy and restless; not suicidal or homicidal; had delusions of unworthiness that she had lost the key to heaven and had committed the unpardonable sin; at times she was very gloomy and restless and required restraint.

When admitted, she was in a condition of marked motor and mental unrest, with pronounced depressive features; the symptoms were progressive and in a few days the clinical picture presented was that of melancholia agitata—marked bodily unrest, wringing of the hands, crying and moaning, walking aimlessly back and forth in her room and voicing delusions of painfully depressed, gloomy and self-depreciatory contents. This state persisted for a week and was followed by a progressively deepening stupor.

At this time the physical condition was as follows: Temperature 98° F., pulsus melancholicus typical, 100 to 110 in the morning, mounting to 120 in the afternoon without a corresponding temperature excursion; peripheral circulation sluggish, hands and feet cold and violaceous; heart-impulse weak, no murmurs, action regular; cutaneous and mucous surfaces pale and anemic; skin leaky and covered with an ill-odored, oily perspiration; lips dry and covered with brown crusts and the teeth with sordes, resembling the typhoid state; pupils react very sluggishly to light and accommodation; patellar reflexes notably heightened as in paresis; facial lines obliterated, expression blank, with occasional painful alterations; mutism absolute; mental and physical negativism marked; tongue heavily furred and coated; bowels obstinately constipated; involuntary micturition and defecation.

The mental condition at this time was that of profound stupor—the acute dementia of Esquirol. Consciousness was deeply clouded, with amnesia for the stuporous period—the acme or critical stage of the disease—which persisted for twenty-six days. During this time, the patient lay prone in bed, immobile and resistant and requiring to be medicated and fed with the feeding tube inserted through the nose.

One week after admission, acute bronchitis developed and persisted for ten days, during which period there were the ordinary constitutional disturbances, and, in the latter stages, a large amount of mucopurulent expectoration. The debilitating effects of this pulmonary incident, superimposed upon the already cerebral asthenic state, doubtless were influential in prolonging the mental disease.

From admission, June 26, 1903, to July 13, 1903, a period of seventeen days, there was persistent insomnia, the patient obtaining but one or two hours of broken sleep during the twenty-four hours. It will be observed, however, that the attack of acute bronchitis above mentioned, and the insomnious period were coincident—a fact not unworthy of mention when we speak of the agrypnia.

And here let me advert for a moment to the subject of hypnotics in psychiatric practice. It seems we are not employing an altogether rational, but rather an empirical therapy in this direction. Speaking from the vantage ground of four years' experience among the insane, where one would reasonably expect to meet with the

more aggravated and obstinate forms of insomnia, I would say that the continuous employment of the narcotizing and depressing agents usually administered during the acute stages of insanity has proved of doubtful utility, and in some instances has produced pronouncedly baneful effects, such as a prolongation of the psychosis and an increased tendency toward secondary dementia, effects like those produced by the earlier methods of treatment of insanity, namely, purgation and blood-letting, that is to say, depressing and debilitating measures. So I would say, be very sparing with hypnotics, chloral, hyoscine, sulphonal and their many kith and kin. Only in the severer grades of insomnia are these agents admissible, for they are toxic, potent and depressing.

The reason why they are not admissible is not far to seek; it is because the conditions with which we are dealing are conditions of cerebral fiber and cell intoxication (from gastric and intestinal auto-intoxication) and inanition as well —the cells and fibers of the central nervous system are bathed in the already toxic and débris-laden fluid of the perivascular spaces and lymph-cisterns; consequently there is a true phrenasthenia—brain debility; hypnotics are all in some measure depressant and are therefore contra-indicated in these states of brain-tissue exhaustion and weakness. Think of administering aconite to a subject with fatty degeneration of the heart or with advanced chronic myocarditis! Think of administering the coal-tar derivatives to subjects of senile pneumonia! Can it be that we are practising the Hahnemanniac folly, "*similia similibus curantur*" by treating depressed states with depressants? When the genesis and causes of insomnia are better understood, it may be that hypnotics will be less frequently and more rationally exhibited.

During the night of July 27, our patient was restless for about two hours in the latter part of the night; with this exception, she was never reported by our night watches as awake at night from July 13 until convalescence. From August 1, improvement became noticeable and progressed slowly to ultimate and, so far as her husband and myself could determine, complete recovery, the psychosis having persisted for four months.

Treatment consisted of measures calculated to improve the general health, to overcome the anemia—the erythropenia and oligochromemia—to flush the convolutions with a better aerated and nutritive-laden blood-stream; to supply the wanting nerve-elements phosphorus and fats; to aid the system to eliminate the products of convolutional and central-fiber disease, namely neurin and cholin and allied toxic débris; and to remove by appropriate measures, fecal and urinous accumulations, the results of the profound melancholic inhibition.

To be more explicit, treatment consisted in the administration of the elixir of iron, quinine and strychnine, and the combination of cod-liver oil and extract of malt given with warm milk—an emulsion not unpalatable and of the highest nutritive value. As a laxative and cathartic, a mixture of the fluid extract of aloes and elixir of cascara, with occasional doses of magnesium sulphate was employed, never permitting the bowels to go longer than two days without a movement. Tube-feeding was practised twice daily for a month, rendered necessary by the persistent paralysis of appetite and muscular and mental negativism.

One fixed idea we kept steadfastly in mind, namely the disease is one of inanition; in the language of Berkeley, "nutritive disturbances of the cerebrum being the principal causative factor (*i.e.*, of melancholia) psychical distress and a sense of woe and uneasiness are the ways by which the brain expresses its lack of proper nourishment;" and, as Romberg long ago declared, "pain is the prayer of a nerve for better blood." Melancholia, we believe, is the wail of an exhausted brain. Therefore along with an abundance of nutritious food, we gave hematics and stimulants, not only to improve the quality and quantity of the blood, but also to force it in more abundance to the starved nerve-centers; and for this latter purpose a combination of synergistic cerebral stimulants was employed, consisting of caffeine citrate, spts. frumenti, and quinine sulphate. Convalescence was slow but noticeable and in four months our patient was recovered. The usual duration of this, the gravest of the various forms of acute melancholia, is from six months to a year and a half in recoverable cases.

We believe, with Shoemaker, that "therapeutics is the superstructure of medical training," and we are endeavoring daily to practise a more rational therapy—with failures, yes, more than enough, but with many happy successes, of which this is a noteworthy one.

Concerning the pathology of this form of psychosis little is known. Edema of the brain has been said to be its characteristic lesion. W. Bevan Lewis' tables are of interest in this connection, as regards the blood-states of stuporous adolescents; he found the hemoglobin reduction ranging from 55 per cent. to 90 per cent.

Berkeley writes: "Nothing definite is known of its pathology (*i.e.*, of melancholia). In chronic cases there are evidences of old anemias, venous congestions of a passive form, edema of the pia and of the brain substance, and even general atrophy of the convolutions."

Whitwell's observations, consisting of "careful measurements of the blood vessels at the base, by the graduated cone, led him to infer the presence of a congenital narrowing of their lumen, associated also with a universal cardiovascular enfeeblement."

David Orr's work, reported in *Brain*, Summer Number of 1902, is a valuable contribution to this comparatively unknown subject of psychopathology. His findings in a case of stuporous

melancholia which came to autopsy were in part as follows: In a section taken from the fronto-parietal cerebral cortex "the great majority of the large and medium pyramidal cells are readily seen to be affected by a central chromatolysis associated with pallor of the nucleus." He also noted "a well-marked perinuclear chromatolysis of the large cells of the anterior cornua" of the spinal cord at its cervical enlargement.

Etoc-Demazy considers general cerebral edema the fundamental pathological change in this condition, as recorded in his classical thesis "Stupidité."

Whatever its pathology, the treatment of this disorder is fairly well understood and consists of tonics, alteratives and eliminants, overfeeding, baths and open-air exercise and the employment of every safeguard against suicidal and homicidal attempts; and, when convalescence is advancing, encouragement and light pleasurable mental diversion are certainly beneficial in hastening recovery. This we consider a rational therapy which, like "Wisdom, will be justified of all her children."

THE FINSEN METHOD.[1]

BY MILTON FRANKLIN, M.D.,
OF NEW YORK;
LECTURER ON ELECTRO-RADIO THERAPY IN THE NEW YORK POLYCLINIC.

Immediately after the introduction of the Finsen method of treating tuberculous diseases of the skin by exposure to the ultra-violet or chemical rays of the spectrum, there arose upon all sides experiments and suggestions with a view to its improvement.

The first apparatus consisted of hollow glass lenticular bodies, filled with water, or weak solutions of cupric sulphate, or pyoctanin. These huge lenses were supposed to fulfil the double function of concentrating the rays of the sun and of absorbing from among them those rays which produced much heat and little chemical action.

It was soon discovered that these glass flasks were impervious to the very rays upon which the efficiency of the system depended, and that the quantity of chemical rays ultimately reaching the patient was so small as to threaten the method with practical failure. At the same time it became evident that no dependence could be placed on the sun as a constant performer, the number of cloudy days on which no work could be carried out proving considerable; and that the absorption from the solar spectrum as evidenced by the Frauenhofer bands left a light in which the chemical rays were not predominant. It was also found that colored solutions absorbed the chemical rays in great quantities.

After fully establishing that no glass produced at the time was capable of transmitting the ultra-violet rays in suitable quantity, it was determined to make use only of rock crystal in the construction of the machines used in the Finsen Institut, and of distilled water in the coolers.

The largest obtainable lenses of rock crystal were about 3½ inches in diameter, and those of that size were extremely rare. The available diameter of the lenses (Medical News, September 20, 1902) determines in a great measure the value of the apparatus. The voltaic arc was found to fulfil all the conditions of constancy and high ratio of chemical rays.

Finsen then devised the familiar form of lamp which has been associated with his name and method. It consisted of an arc lamp of fifty ampères capacity, suspended vertically. Around this were disposed four telescopes so arranged as to collect each a portion of the light generated in the arc, and pointed outward and downward, the axis of each telescope lying in a vertical plane forming an angle of 90 degrees with that of the next adjacent. At the proximal end of the telescope was placed a lens whose function was to refract the divergent rays from the arc into a parallel pencil within the barrel of the telescope where there was a quantity of distilled water through which the light passed, and in which most of the heat radiation was absorbed. At the distal end was a system of lenses which caused the rays to again converge into a focal point of about one-half inch diameter, and at a distance of three inches from the end of the telescope.

In this lamp there were inherent many defects of principle; chief among which were the great distance of the condensing or collecting lenses from the arc, rendering the amount of light utilized in each telescope very small; great length of telescope, with long air spaces; and faulty disposition of the axes of the telescopes, failing to collect the light at the angle of greatest intensity.

This was, however, the first practical lamp, and with it the method was initiated. There was manifested on every hand a disposition to criticize the imperfections in the Finsen apparatus and to substitute other designs, which were alleged to possess features of superiority over the original.

The necessarily great duration of the treatments, one and one-quarter hours, and the cost of installation and current were the cause of much adverse comment. Most of the new apparatus suggested was for the purpose of so economizing the energy by superior physical design that much smaller lamps could be used, and at the same time the result be obtained in shorter periods of exposure.

Among the more noticeable of the improvements was the lamp invented by Sophus Bang, then an assistant in the Finsen Institut. The original contained a small arc of three ampères capacity maximum, supplied with iron electrodes. The smallness of the light was compensated for in the nearness of the arc to the surface to be treated, and in the simplicity of the optical system, which consisted of a single quartz disk.

[1] Read before the Clinical Society of the New York Polyclinic, October 3, 1904.

The elimination of heat was effected by the ingenious expedient of rendering the electrodes hollow and causing to flow within them a stream of cold water. In this way a light that was quite cold was obtained. This lamp produces a cutaneous reaction in fifteen minutes. The quartz disk was used as a compressor by being applied with force to the skin, thus reducing the armamentarium to its simplest dimensions. The selection of iron for the electrodes resulted from the fact that the spectrum of iron contains lines further up in the ultra-violet than that of any other commercially obtainable substance.[1]

The Bang lamp was the type of numerous others, principally the Kjeldsen and the Dermo.

Another type was that invented by Lortet & Genoud and variously imitated by Foveau de Courmelles and others, in England and in this country. This consisted of an arc of 15 ampères capacity, having the carbons set at an angle of 90 degrees and placed behind a double metallic shield, between the layers of which circulated cold water. Each layer of the shield contained a small window in the center, completing that part of the water bath. The arc was placed directly behind the posterior window. The advantages claimed for this lamp were that the proximity of the light to the area to be treated rendered larger capacity needless, lightness and elimination of the difficulty and expense of procuring large rock crystal lenses. The outer disk was pressed against the lesion, thus serving the office of compressor.

Perhaps the most important of all these modified lamps was the spark-gap lamp suggested by Goerl and perfected by Professor Piffard. This, in the latter form, consists of a holder of vulcanite on which are mounted small iron spheres between which are air spaces. The two outermost of these are connected with the terminals of a capacity which is in communication with a static machine or coil. When the latter is operated a continuous stream of brilliant discharges takes place between the iron spheres emitting an intense light with little heating and possessing what is probably the greatest known photochemical action. In front of the spark-gaps is placed a rock crystal disk which, when pressed against the lesion, furnishes the required compression. This lamp gives a reaction in a shorter time than any other, ten minutes or less, sufficing in most cases, to cause a dermatitis.

I omit descriptions of many ludicrous machines produced in this country. Suffice to say that any machine employing glass in any part through which the rays are obliged to pass, is faulty in theory, for notwithstanding the statements of the makers to the contrary, there is no known formula for glass that will transmit the ultra-violet rays in quantities practical for utilization in photo-therapeutic practice. The so-called ultra-violet vacuum tubes to be found in the catalogues of many makers are the fruit of ignorant hypothesis and not worthy of serious consideration.

With all these methods of reducing the cost and duration of the treatment, and of increasing the efficiency of the apparatus and treatment generally, it is remarkable that the Finsen method has steadily declined in the amount of attention attracted to it in different countries. From having been heralded as the most remarkable and important medical discovery of the age, it has gradually fallen into disuse until, to-day, there are many erstwhile enthusiasts who are ready to admit that they have failed and abandoned the method.

In a recent trip abroad, I had the opportunity of seeing much of the work that was done at the Lysinstitut at Copenhagen. What I saw there has given me an entirely new view of the whole Finsen method, and explained to a great extent the cause of its decline in other countries. Here alone of all the countries where it has been tested, have they never lost sight of the primal reason for which it was invented. The original idea, to cure lupus vulgaris by means of the chemical rays of light, has been steadily adhered to, and the result is that they have achieved a success that is certainly remarkable. The number of cases in which they fail is negligible, and may be confined to those of long standing where the skin is impaired beyond regeneration.

The treatment has been continued with the faith, not of the fanatic, but of the scientific logician who recognizes no difference between theory and practice, where the theory is sound.

In my estimation, the reason why interest has been lost in the Finsen method outside of Denmark is to be found in the fact that the host of those who have taken it up have been ill prepared to grasp a subject whose accurate understanding required a knowledge of the physics of optics and electricity. With such a knowledge many of the ridiculous errors in designing apparatus would never have been made. In the constant endeavor to simplify the apparatus, the method has departed far from the original principle.

At the Finsen Institut constant efforts were made to simplify the apparatus, but nothing was accepted without having proven, in fact as well as in hypothesis, its superiority. The reason for their success is that they retained the old imperfect apparatus which, by the way, had demonstrated that if given time it would do the work, instead of accepting on the word of the enthusiast every little toy that was heralded as better than the original.

Much skepticism and lost interest in the method is due to the misguided desires on the part of the ignorant to invade all fields with the

[1] The least wave length of any iron line is 2983.640 and the intensity is 0000 N (Rowland). The shortest line of any appreciable intensity is the 2990.523 line with an intensity of 1. From there to the 3047.725 line, whose intensity is 20 N, and which is the most important iron line in that part of the spectrum, the iron lines are numerous and vary in brightness from 000 to 4 or 5 and even 10 in the 3037.510 line. There are other shorter wave lengths of other substances, but they are of lesser intensity.

light. At the outset, the too well-known tendency on the part of some persons manifested itself in the premature publication of pure hypotheses having no basis in experiment, and not even the substructure of sound physical theory. The lay press has fostered this tendency in its quest for sensation, and the result is that much of what was promised for the sunlight panacea has not materialized, and the interested spectators of the outcome are disappointed and inclined to regard the whole as a failure.

At the Finsen Institut there has been no wild speculation as to fabulous cures. The abstruse education and knowledge of the director forbade any fanaticism. The treatment was originally invented for the cure of lupus vulgaris, and that fact has never been forgotten. At the Finsen Institut there has been more experimenting on different diseases than anywhere else in the world, but nothing was claimed until it was absolutely proven. At the same time a lot of futile experiment was saved by the fact that the man in charge was fully familiar with the principles of the science.

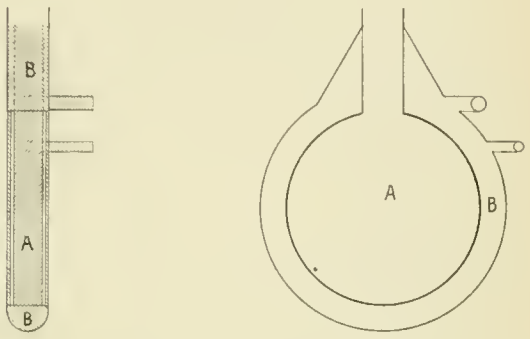
The Institut at Copenhagen has been the scene of incessant research on the subject of the improvement of apparatus. Every logical type of lamp suggested elsewhere was carefully tested and rejected only after proving inefficient.

At present there are two lamps used at Copenhagen, which are unquestionably efficient and possess all the advantages of economy and celerity consistant with the physical limitations represented by material obtainable. These are the Finsen and the newer Finsen-Reyn lamps. The former is to be preferred in institutes and hospitals where a large number of cases are treated, and the latter, where the number is small.[1] The principle upon which these machines is based is that no known glass is capable of replacing the rock crystal for transmitting the chemical rays, and that therefore every economical machine must be no larger than the size of the quartz lenses obtainable warrants.

Experiment has demonstrated that at an angle of 56 degrees to the axis of the positive carbon, the rays are more abundantly distributed than at any other at which they may be conveniently collected.[2] In both lamps the optical systems are arranged at this angle. The Finsen-Reyn possesses some latitude of adjustment in the barrel, useful in the smaller lamp.

The larger lamp consists of a 50-ampère arc, with four telescopic tubes containing optical systems, as already described. The improvements consist in having the tubes inclined at the angle of greatest intensity of the rays, and in having the condensing lenses as near the arc as their diameters will permit. The cooling apparatus is improved and merits description. The outer component of the condenser consists of a hollow disk-shaped chamber of rock crystal. (Fig. 1.)

Fig. 1.

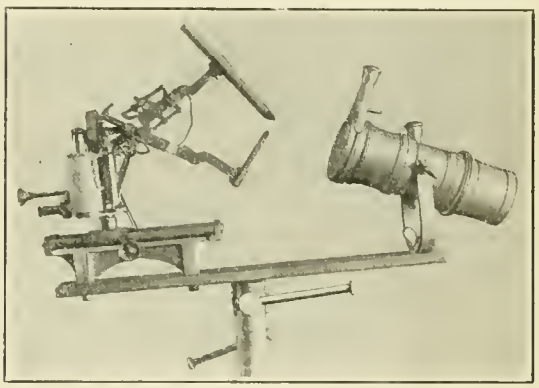


Details of Cooling Chamber.

Water is contained within (A, Fig. 1), which does not circulate. Around the edge of the chamber (b, Fig. 1), running water absorbs the heat from the still water. In this manner, flowing water in the path of the rays is eliminated. An important consideration, as demonstrated by experiment.

I give a brief description of the Finsen-Reyn lamp (Fig. 2), one of which I have secured from

Fig. 2.



Finsen-Reyn Lamp.

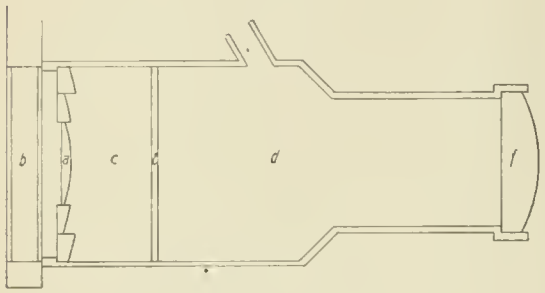
Copenhagen, it being of interest to practitioners in this country, where lupus cases are not numerous. Its small size, high efficiency and low current consumption recommend it. This consists of an adjustable iron base upon which is mounted an optical table about 22 inches long. At one end of this is an arc of 25 ampères capacity. This is fully adjustable and automatic. The carbons are inclined to each other at an angle of 120 degrees, the upper forming an angle of about 56 degrees, with the optical system (Fig. 3) mounted at the other end of the table. This is a barrel 10 inches long, mounted on trunnions in a swivel, and containing the lenses and

1 The ratio of efficiency is greater in the smaller lamp than in the larger (about twice greater, for with a current of 25 ampères, the effect is equal to that in the larger machine in each telescope with 50 ampères, but the total economy of the larger machine with four tubes, is twice greater than that of the smaller with but one).

2 This is not the best angle intrinsically, but the best at which the rays can be collected in a practical lamp.

cooling apparatus. The condenser is guarded by a cooling chamber similar to that of the large Finsen lamp (*b*, Fig. 3), the thickness of the layer of water being three-quarter inch. The

Fig. 3.



Plan of Barrel.

condenser (*a*, Fig. 3) is composed of concentric sections of rock crystal cemented together. Each section has a different focal length, thus securing a greater critical angle and collecting more light than would be possible with a simple lens. Between this and the large chamber is an air space (*c*) two inches long. The large cooling chamber (*d*) is six inches in length. The water in this is not changed during treatment. At the initial end of this chamber is a flat disk of rock crystal (*e*), and at the distal end is a convex lens (*f*), which brings the rays to a focus at 2½ inches from the instrument. All the lenses and disks are of rock crystal, and have a clear aperture of 3¼ inches. The light is delivered by this machine at a temperature of 110° F., and is further cooled in the circulation of a compresser of the ordinary type.

The objection is offered at the Finsen Institut that all forms of lamp employing high tension sparks and iron arcs give only a violent superficial reaction of such severity that the treatment must be discontinued after a short time. The light from these does not penetrate, and when the surface burn heals, the nodules are far from cured. This accounts in a great measure for the numerous recurrences that have been observed in cases supposed to have been cured by the X-ray and iron and spark lamps. It is certain that a material period of time is absolutely essential in the treatment, and that any attempt to curtail this results only in violently affecting the upper structures at the expense of those deeper. The successful practice of the method requires a slow, even, effect gotten through a great depth of tissue. Nature requires a measured length of time to react to the stimulus of the rays, and this cannot be shortened.

Of the modified lamps, that due to Professor Piffard is, as has been already stated, the most important and successful. But the results have been almost altogether in cases of lupus erythematosus and other superficial conditions. In fact, it may be said that for lupus erythematosus, the results obtained by this form of apparatus are far superior to those obtained by the Finsen lamp, and the recent discovery of a new form of radiation in his lamp by Dr. Piffard, may lead to further development along these lines.

In conclusion, I think that the Finsen method when properly practised, and this necessitates the employment of suitable apparatus free from glass and of sufficient power, is superior to all known procedures for the treatment of lupus vulgaris. This opinion is the result of a close observation of the results obtained at the only place where the method has been properly employed. The use of the X-ray has been too limited to warrant the positive assertion that it is a specific in lupus. The cases that have been positively cured by the Finsen method are almost without number, while those cured by the X-ray are few and scattered, and their authenticity shrouded in uncertainty. It may be that we shall finally find a valuable therapeutic agent in the high-frequency currents, but in the meantime we have the ultra-violet treatment of Finsen.

112 West Forty-seventh Street.

THE ANTISEPTIC TREATMENT OF THE PUERPERAL WOMAN.[1]

BY LOUIS KOLIPINSKI, M.D.,
OF WASHINGTON, D. C.

Ars summa, materiâ optimâ melior. Quintilian.

The woman delivered of the new-born child is a surgical subject, the victim of wounds of the contused and lacerated varieties of the uterine cervix, the vagina and its outlet. They may be extensive, they may be slight, they are always present. These injuries, when not protected by art, are the chief cause of puerperal infection, septic, puerperal or childbed fever. This fever with a misinterpreted, voluminous and controversial record has of late years diminished much in mortality, but, as some say, not in morbidity, due to anomalous methods of prevention and treatment. In principle these methods are more or less correct, namely the existence or maintenance of the state of local asepsis. This condition is achieved in part by the protective power of nature over the woman, the acid state of the vagina, in the sterile lochial discharges expelling minute organisms or yielding but a barren soil for growth, and is further secured by the antepartum cleansing of the patient, local and general, by the cleanliness of the nurse, by the attention to the clothing, the person, the hands and the instruments of the obstetrician. Further the injuries are to be kept germ-free postpartum by a cleansing of the external genitals, by a single vaginal douching to remove blood and clots, by the use of vulvar pads or lochial guards, frequently replaced, and by an occlusive dressing. This much and so far, in the opinion of the writer, is not enough. The fact remains that a superficial torn wound of this or any other

[1] Read at the Therapeutic Society of the District of Columbia, October 8, 1904.

part of the human body requires surgical treatment, which is in its action both curative and preventive of any other pathological process. One of the best, in thoroughness and efficiency, is irrigation, which embodies the essential act of drainage.

Douching the vagina is a form of this. It has been extensively tried on the lying-in woman and has been generally abandoned as both inefficient and harmful, productive of the very complication it was intended to keep away, and increasing the death-rates of obstetrical hospitals in a marked degree. It has grown to be feared as a maker of mischief almost as evil as when used intra-uterine or as is the curette when septic fever is active. Nevertheless the principle of the occlusive vulvar pad, in theory and collateral experience, has not much to commend itself when the problem of treatment is the prevention of the infection of a wound so prone thereto as is that of the woman just delivered; from its location, position, its anatomical and physiological surroundings.

Again, the minute and exact details of precaution to which the physician subjects himself, the nurse and his implements are very much overdone and overtrusted. A wound that is under the full stream of an antiseptic fluid cannot be infected by the accidental contact of the attendant or an instrument in its ordinary state. The mode and vehicle of contagion is the ordinary and every-day contact and exposure of a wound not protected and preserved, and not the rare and extraordinary modes of inoculation, such as from hands contaminated in the dissecting room or at an autopsy. This insistence on the unusual was perhaps the chief cause of the want of appreciation shown the discovery of the unfortunate and derided Semmelweiss.

In the treatment of a wound by irrigation where tissue is necrosed, half dead or of low vitality, the liquid in its general or local action must not be poisonous and its quantity must be unlimited. Its action must be like the continuous flow of surgical practice. Undoubtedly the unhappy attempts at vaginal douching were and are due to blunders in these fundamental requisites. Such blunders are: First, the use of corrosive sublimate, of carbolic acid or of some of its pseudo-scientific substitutes, and, second, expending a very limited supply.

The writer has used antiseptic douching in normal puerperal cases, and the effects are found to be in every way satisfactory, both in the feeling of general comfort to the patient and in the avoidance of septic fever or its speedy destruction. He has followed the rule that it is better to flush with too much rather than with too little, and accordingly the method consists in washing out the vagina, the cervix, and the vulva, the patient being in the proper position, with a gallon of a solution of boric acid in boiled tepid water, made in the proportion of a heaping teaspoonful (1½ drams) of the powdered acid to the pint. This is repeated three times a day for the first week and then discontinued altogether. Septic fever has not been found to appear in any normal case, and the patients are very well satisfied, particularly so when the purpose of the douching is explained in the beginning. The antiseptic vulvar pad is dispensed with or its use left to the discretion or wish of the nurse or patient.

Boric acid is the most suitable antiseptic, as it has none of the objectionable side effects of other therapeutic bodies of its kind. Its superior suitability can be admitted without argument, and it is the active agent in a number of much used and much advertised nostrums of the "ethical" kind.

To achieve a satisfactory afebrile course in a lying-in woman, barring, of course, the normal rise of one degree and a fraction, three douches a day are sufficient. Two will be found to answer one's ordinary expectations, but four repetitions are not too often, and make the result all the more sure.

To conclude, the writer would wish the much-blamed, much-mistrusted antiseptic vaginal douche in the puerperium not to be completely damned on its past record, but to be used with confidence, by those so inclined, in the way here described, after the manner of a prolonged irrigation and in a quantity neither scant nor limited.

It is a very doubtful statement to maintain that in the obstetrical or in any other practical medical art, nature should be entrusted in civilized life with the care of the patient to keep her free from fever, as nature is unfortunately much more often the cause of fever than is man.

CEREBRAL PALSIES IN CHILDREN.[1]

BY J. M. AIKIN, M.D.,
OF OMAHA, NEB.

THE palsies of children naturally fall into one of two types, clinically known as cerebral and spinal. We see them as hemiplegias, diplegias and paraplegias. The spinal type is so well known clinically and pathologically that I will not refer to it except for differential diagnosis from the cerebral type.

The seat of the lesion in the cerebral palsies of children, as in the adult, is in the brain. It is in the central motor neurons, and in the part of the brain that connects the cortex to the spinal anterior horns. Dana very aptly names these tracts corticospinal neurons and reserves the name neurospinal neurons for the parts degenerated in the simple spinal palsies of childhood. Statistics are not available for accuracy of statement on the relative frequency of cerebral palsies in childhood and adult life. The frequency of cerebral as compared to spinal palsies in childhood, however, is about equal. Our best reports give relatively as large a ratio of cerebral palsies in childhood as in adult life. At first thought

[1] Read before the Omaha (Douglas County) Medical Society, at Omaha, Neb., Sept. 27, 1904.

this statement may seem wide of the truth, but analysis of the etiological factors will, I think, relieve all doubts.

Cerebral palsies in childhood are resultant to prenatal defects, birth accidents and postnatal causes. The vast majority occur during the first three years of life. About one third are congenital in origin; that is, the child is born with cerebral defects, with a lessened number of cortical cells and pyramidal fibers than a physiologically developed child should possess as a basis on which to commence its extra-uterine growth. These are unfinished children, mainly because their progenitors were deficient in vital force. The most common birth accident is prolonged labor. Cerebral palsies from this cause are more frequent in the younger children of a family and from a young wife whose aged husband can impart only the dregs of manhood to his offspring.

In such children the life current is impoverished, the vascular system has less resistive powers, and hemorrhage into the meninges is coincident with, or follows soon after birth. The pathology is not particularly characteristic. It is the clinical sign and its course which make this an independent disease. Pushing the parietal bones against each other is said to cause a compression of the longitudinal sinus, by which the entrance of blood into the veins is made difficult and arterial congestion favored. Forceps delivery is blamed, but it would seem, unjustly, for it appears to be not so much the use of the instruments that is responsible as the factors which render their use necessary. The injuries by accident at birth are to the vessels of the meninges causing lesions over the motor zone of the cortex. Of the postnatal etiological factors, scarlet fever with nephritis, measles and pneumonia with endocarditis and embolism and whooping-cough are common causes of vascular lesions preceding cerebral palsies. Although the motor zone is the initial point of the cerebral attack, the process is diffuse, involving intelligence and the special senses.

Symptoms.—An initial period of fever and convulsions extending over several days, or even weeks, is early followed by motor paresis or paralysis involving one-half of the body, and an upper or a lower extremity. In the infant and young child a lessened though not abolished motor power is apt to be overlooked by physician and nurse until the child has so far recovered from the acute attack as to make efforts at voluntary muscular movements. Even then, impaired motor function and awkward movements are attributed to a simple weakness common to the convalescent period following any acute febrile attack. If convulsions were a constant initial factor, cerebral palsies would not so frequently be mistaken for spinal palsies. Contrary to our belief of former years, more accurate clinical observation has shown that more than one half of the corticospinal neuron lesions are unattended by convulsions as an early symptom; wheras not a few of the neurospinal palsies are preceded or accompanied by them. Within a few weeks after development of the paralysis, improvement will be seen, first in the face, then in the leg, and last and least in the arm. Encouraged by this we too often venture a prognosis that the child will outgrow it all. Up to this stage of progress a period of two to six weeks had elapsed and the points for differential diagnosis from the spinal palsy are just developing. If three or four days are sometimes necessary to differentiate the exanthematous diseases, or a continuous fever, a period corresponding to as many weeks is frequently necessary for deciding between a cerebral and a spinal palsy of childhood. Early after the paralysis is established spasticity of the muscles and exaggerated tendon reflexes develop. To the careless observer, spasticity of the muscles may be looked upon as a tremor due to weakness; this condition of spastic movement in the muscles diverts us from detection of an increased tendon reflex. Some but not decided muscular wasting and contractions are to be seen in the affected limbs, developing later into permanent contractions. Choreic and athetoid movements are a common occurrence. In the spinal type, paralysis is followed by flaccidity of the muscles, diminished or lost tendon reflex, marked atrophy of the muscles and entire absence of purposeless muscular movements. In the cerebral type the mental condition is disturbed. It is usually backward in development, the degree of mental defect ranging all the way from feeble-mindedness to imbecility and even complete idiocy. The development of peculiar moral traits associated with low degree of intelligence distinguish these children among their associates. Approximately one in four have a fair degree of intelligence, but a larger number are slow in learning to talk. In a very small per cent. of cerebral palsies those in which the face and arms are not paralyzed or only slightly, where both legs are involved, the intelligence is not impaired. As the child grows older improvement in the use of the legs occurs, but spasms of the flexors and adductors cause the legs to cross each other in attempts at walking.

This form of cerebral palsies in childhood is sometimes known as Little's disease. In the cerebral palsies the muscle reaction to the electrical current is normal. In the spinal type degenerative reactions are present. Palsies which are congenital, not attended by difficult labor and where there have not been convulsions or other serious phenomena after birth, are most likely due to true porencephalus. Palsies occurring during the first thirty-six months following birth are commonly due to cerebral hemorrhage, embolism or thrombosis. Of these, hemorrhage takes first place, embolism second, with thrombosis as a factor not yet clearly established. A case of cerebral hemorrhage in a two

months old child, on whom I did a post-mortem about twelve years since, verified our clinical diagnosis of a truth not at that time generally accepted by the profession, namely, that cerebral hemorrhage does occur, and frequently too, in children. I had attended the mother when this child was born; she was an alcoholic and morphine narcomaniac. The confinement was normal, labor lasting about three hours. The babe was full term and apparently healthy. It was wholly a bottle-fed child. A brief febrile attack with digestive disturbance was followed two days later by local muscular twitching on right side of face and right arm. These spasms were variable in degree, but increasing in severity and extent until, twenty-four hours after, right hemiplegia was established, death ensuing one week subsequent to the initial febrile stage. The autopsy revealed a hemorrhage of the left middle cerebral artery. Heredity doubtless had a large part in giving that child degenerate arteries. "We are just as old as our arteries."

Course and Prognosis.—The cause is chronic in both types and cure is scarcely possible. In the cerebral type mental defect exists in more than 90 per cent. of the cases. Epilepsy develops in one-fourth to one-half of all, and athetosis or some purposeless movements are commonly present.

In the spinal form mental impairment does not follow, nor do convulsions return after the initial stage. Differentiation of a cerebral from a spinal palsy in children is not easy at the onset, but when weeks pass into months, the numerous points of distinction are too clear to admit of an error in diagnosis. When the diagnosis is clear, we should unhesitatingly advise the parents or guardians regarding the prognosis. It is not enough to say that the impaired motor power will never be fully restored; we should clearly indicate the mental defect so likely to appear in the cerebral type, before allowing a devoted parent to spend money for need of which other members of his family are suffering, in a futile attempt at educating a defective and degenerating brain to the degree of earning a living by his intellect. In a simple spinal palsy the possibilities for receiving mental training are on a par with other healthy children of even age, the spinal palsy *per se* is no barrier to intellectual culture.

MEDICAL PROGRESS.

SURGERY.

Use of the Segmented Ring in Gastric and Intestinal Anastomosis.—The use of the segmented ring in gastric and intestinal anastomosis, as described in 1902 by Francis B. Harrington, of Boston, received such favorable encouragement from the profession during the past two years that reports have been made of personal cases to date, together with the results of a series of experiments upon animals, showing the process of repair. The ring, as described by FRANCIS B. HARRINGTON (*Annals of Surgery*, November, 1904) is made of hard aluminum in four sections, the sections being joined together by a small bar of steel, which has a shoulder and screw-thread serving as a handle. The outer surfaces of the ring are grooved to hold the ends of the intestines, which are tied in place by catgut purse-string sutures. The segments fit together by means of sliding tongue and groove joints, so rounded that they will not cut or catch in the tissues. The ring is made in three sizes, the middle size being best adapted for general use. The smallest size is well adapted for children and for cholecystenterostomy. The objects of the ring are to mechanically assist in the rapid and safe anastomosis of the intestines and to make the contrivance collapsible into such small pieces that subsequent passage through the intestines would be devoid of all danger and pain.

End to End Anastomosis.—Clamps are applied in the usual manner a few inches from the field of operation, and a gather stitch of No. 2 plain catgut is placed on either side of the area to be resected FRANCIS B. HARRINGTON (*Annals of Surgery*, November, 1904). This stitch circles the intestine with bites deep enough into the muscular coat to insure its not slipping, and in order to save time later, the catgut is lightly tied with one-half of a surgeon's knot without drawing the purse-strings tight. The bowel is next cut away up to one-eighth of an inch from the gather stitches because a wide margin forms a wide inturn and a correspondingly thick scar. The weak point in mechanical aids is the difficulty in obtaining a secure joint at the mesenteric border, which danger is avoided with the ring, by putting in a mattress stitch at this spot. This stitch includes a portion of the mesentery on each side, but is not tied at once. The ring is now introduced and one gather stitch tied. The mattress stitch is next tied, followed by the tying of the second gather stitch. The cut bowels now lie smoothly end to end, and by use of the handle can be easily moved about in convenient positions for sewing. The main stay of the suture is a Cushing's continuous stitch which penetrates the bowel into muscularis mucosæ. This starts just to one side of the steel handle and passes around the intestine with frequent knots until it reaches the handle again from the other side. The handle is now unscrewed, leaving the ring held together by the purse-strings, and the suture continued over the hole just occupied by the handle. The cut edges of the mesentery are caught together by a few interrupted stitches. The gather stitch consists of two parallel arms crossing at one end; these arms are just wide enough apart to allow room for incision. The mattress stitch is omitted here, and a continuous stitch is employed to approximate the serous coats and form the anastomoses. The results obtained both practically and experimentally have been most encouraging.

Foreign Bodies in the Vermiform Appendix.—L. J. MITCHELL (*Med. Rec.*, December 10, 1904) gives a list of true foreign bodies found in the appendix during his service as Coroner's Physician, with 1,600 autopsies. One or more grape seeds were present in eight cases, one or more shot in three cases, and fragments of bone in two cases. Other objects were a portion of a shingle nail, a globule of solder, a piece of nutshell, a portion of the vertebral column of a small fish, and fragments, apparently, of ash or stone. None of the appendices containing these bodies showed any igns of inflammation either past or present.

Resection of the Epididymis for Tuberculosis.—From data at present available and also from 12 cases treated by himself, W. Bogoljuboff (*Archiv f. klin. Chir.*, Vol. 74, No. 2) concludes that these are not yet numerous enough to compare the results of this operation with castration. Removal of the tuberculous epididymis is followed in a large percentage of cases by the cure of the process in the testis and recurrences in the testis are not common. Partial resections of the epididymis are attended apparently by a less favorable prognosis as regards the cure of the process in the testis or the epididymis, than the complete resection. Removal of the tuberculous focus in the testis together with resection of the epididymis, not uncommonly leads to a cure of the process in the testis itself. The testis, although deprived of its epididymis, can retain its gross normal relations for a long time. Involvement of the other testis does not apparently occur any oftener where the resection of the tuberculous epididymis is done, than in those cases where no operation has been done. Bilateral, as well as unilateral resection of the epididymis in certain cases may also exert a favorable influence on a tuberculous process in the prostate or seminal vesicles. A tuberculous process existing at the same time in the lungs, may also be affected in a similar manner. The ability to indulge in coitus is retained after either one of these operations. The author finally observed that the production of an anastomosis, by operation, when resection of the epididymis was done, did not unfavorably affect the prognosis of the latter.

High Position of the Scapule.—The various forms of high scapular posture are met with quite often, and familiarity with them may save both the physician and the patient many a trouble. A. A. Vorobyoff (*Roussky Vrach*, No. 35, 1904) cites two cases, in one of which the deformity was of an hysterical origin but so stubborn that the patient, otherwise a perfectly healthy man, was freed from military service after three and a half months of close observation in a hospital. While under chloroform the deformity could be reduced until both shoulders appeared perfectly normal. But even during the process of waking up from narcosis the scapulæ and the shoulder-joint gradually slipped back into their former position. In the second case the deformity was due to a congenital torticollis in which an operation performed some years ago, placed the head in a normal posture but failed in any way to influence the position of the scapulæ. The shortening of the left sternocleidomastoid muscle, its influence on the function of the clavicle and the entire half of the shoulder-joint became clear from the history of the disease. Such cases are not rare, as it is a well-known fact that at a certain stage of torticollis the scapulæ, as well as the entire shoulder of the affected side, takes in a higher position, at times even touching the corresponding ear. The author draws the following conclusions: (1) High position of the scapulæ as an independent affection and may be either acquired or congenital. (2) The congenital variety, as described by Sprengel, depends principally on bony changes of the scapulæ or alterations in the muscles inserted into it. Kaush has demonstrated the importance of the lower portion of the trapezoid muscle in the etiology of this affection. (3) The acquired forms depend on rachitic changes in the bone of the scapula itself. The first case described by the author belongs to the acquired type in which the affection of the muscles was due to muscular dystrophy. (4) Cases of congenital or acquired high position of the scapulæ in which its position is to be ascribed to causes not to be detected in the bone itself or in the neighboring muscles, should be strictly distinguished from the variety of Sprengel and from similar affections.

Anesthetic Effects of Methyl Oxide, Ethyl Chloride and Somnoform.—It is self-evident that our present anesthetics are not, by any means, satisfactory and that we should, as soon as possible, reach some definite conclusion as to the value of these newer substitutes for chloroform and ether. F. W. Hewitt (*Lancet*, November 26, 1904) concludes, (1) as to methyl oxide that when it is largely diluted with air, the mixture, which is not unpleasant to intake, rarely produces satisfactory anesthesia. Mixtures sufficiently concentrated to give such anesthesia are too pungent to be pleasant. As compared to the anesthesia obtainable by ordinary methods, that produced by methyl oxide is of a light type, although it is not infrequently followed by nausea and other distressing symptoms. In other words, although a long administration may lead to a long anesthesia, unpleasant after-effects are apt to follow. Analgesia is often difficult to produce to a satisfactory degree. Danger, however, is almost unknown in the use of this drug. Ethyl chloride, under certain conditions may be a very useful anesthetic. It is a fairly good substitute for nitrous oxide, but it is unquestionably somewhat uncertain in its action, depending apparently upon the reaction of the patient to the drug, a factor which cannot be determined until after it has been administered. Its chief drawback lies in the frequency with which it produces bad after-effects, headache, nausea, vomiting and a miserable sensation of depression. These are apt to be very characteristic and almost typically significant of even a moderate dose of the chloride. A feeling of heat is not uncommon. Speech disturbances are less common than with nitrous oxide, although micturition seems a trifle more common under the chloride. It is distinctly inferior to nitrous oxide and oxygen for short operations, such as dental work, although its portability and simplicity of administration constitute important advantages. The continuous administration without deep breathing of percentage mixtures of ethyl chloride and air, does not produce the best type of anesthesia. By adding nitrous oxide to ethyl chloride a very deep form of anesthesia is induced with extraordinary rapidity, the method having the advantage of destroying consciousness more pleasantly than ethyl chloride alone. The so-called somnoform does not produce such good effects as pure ethyl chloride and is distinctly more dangerous.

Stricture of the Urethra.—The subject of urethral stricture is not, perhaps, one calculated to excite any great degree of originality, but it has certainly been illustrated by Watson (*Boston Med. and Surg. Jour.*, December 8, 1904) with a wealth of experience. He points out very rationally that urethras cannot be measured according to a certain arbitrary worm, inasmuch as they are not naturally all of one caliber. Nor can the meatus be taken as a guide of the urethral caliber. The average caliber may be said to be 32 French, but there are considerable normal variations, more of them above this figure than below it. The average meatus measures 22. There seems to be a fairly constant relation between the circumference of the flaccid penis, and the caliber of its urethra. Otis found this to be so, that a penis with a circumference of three inches, has a urethra with a caliber of 30 French, and each quarter inch in the increase of the circumference, means a corresponding increase of 2 mm. in caliber. In treatment, he believes that webbing bougies, sterilized in a saturated solution of rock salt, should be used up to 18 or 20 French, and from then on metal sounds. The operation of internal and external urethrotomy is described as used by Dr. Gavin, and said to take "not more than two minutes." For the rest, the orthodox methods are described.

PHYSIOLOGY.

The Proteolytic and Rennetic Functions Belong to the Same Ferment.—The knowledge of the extreme and baffling complexity of the digestive ferments is still further complicated by the discovery that actions which have hitherto been attributed to distinct enzymes, really belong to one and the same ferment. This discovery was made by J. P. PAWLOW and S. W. PARASTSCHUK in a study of the reciprocal relations of the proteolytic and milk-coagulating forments (*Hoppe-Seyler's Zeitch.*, September 22, 1904). The actions of both of these ferments in the various digestive juices follow a parallel course. All those changes that influence the functions of the peptic glands, effect both proteolytic and rennetic processes to an equal degree. Age has the same effect. The gradual elevation of the temperature to 52° causes both ferments to gradually and equally diminish in power, which is entirely lost at 62°. The addition of intestinal juice to pancreatic juice activates both the proteolytic and rennetic functions of the latter to an equal degree. A similar parallel course is seen in the juices obtained from the pyloric portion of the stomach and from the region of the duodemum provided with Brunner's glands. The latent and active conditions of both functions are similarly affected in all the juices examined. Upon these grounds the authors attribute these actions to one ferment. A preparation of rennin which Mencki has examined and which he had found possessed the property of coagulating milk, but not the property of digesting fibrin even when acidulated and diluted ten times, was found by Pawlow to digest fibrin when diluted a hundred times with .2 per cent. hydrochloric acid. What is the significance of the coagulation of milk from the standpoint of digestion? If the presence of rennet in mammals be considered necessary for the digestion of milk in the intestine, its function in other animals and in plants in which rennin is present, would be a very incomprehensible one. What would be the use of rennin in animals and plants, when it never comes in contact with milk? The best answer to this question is that the coagulation of milk is a special and from the standpoint of the experimenter, an accidental expression of a general reaction. This conclusion, which is credited to A. Danilewsky, also regards the coagulation of milk as a complication of the proteid molecule, corresponding to a simplification of the latter by means of pepsin, etc. The curdling of milk is the simplest stage in the long series of syntheses of proteids.

The Use of Reducing Substances in the Study of the Distribution of Poisons and Their Effects in Cellular Activities.—Of eminent practical importance from the standpoint of pharmacology and physiology, are the results obtained by C. A. HERTER (*Hoppe-Seyler's Zeitsch.*, September 22, 1904) in studying the effects of various poisons on the reducing activities of the tissues. The method used has been little applied in these branches of science. It was devised by Ehrlich and consists of the injection of methylene blue into the veins of some animal; in a few minutes, either during the life or shortly after the death of the animal, the methylene blue in the various tissues, depending upon the reducing strength of the latter, is partly or wholly decolorized into its leuco-base. This reduction shows itself in a change in color of the tissue from blue to its natural shade. Some of the tissues remain quite blue. The conditions are very variable and depend upon a number of factors,—as size and species of animal, quantity of substance introduced, condition of the infusion and interval of time between the injection and the examination of the organs. The author studied the effects on the reducing powers of the tissues of various narcotic substances, carbon dioxide and adrenalin, as well as the action of cold. In a normal animal, killed five minutes after the injection of a certain quantity of methylene blue into a vein, the muscles showed little of the dye, the lungs are wholly unstained and the heart, particularly the right side, has a bluish tinge. The liver has its usual color or appears darker than normal, the bile is green and contains both reduced and unreduced dye, the pancreas is stained light blue, and becomes considerably darker in the air. The kidneys are stained quite dark and get darker in the air. The urine is stained a greenish blue. The brain is nearly entirely unstained, as are likewise the suprarenal capsules. With the injection of much larger quantities of methylene blue, the phenomena are quite different. The gray cortex of the brain when exposd to the air, acquires a deep blue color, and the islands of Langerhans are deeply stained, while the rest of the pancreas takes a pale stain. From the fresh organs may be recovered a small amount of the leuco-base, which by means of oxidizing agents, may be transformed into the dye. Only a small part of the coloring matter may be recovered in this way, the greater part remaining in the organs, particularly the liver and bile, as a colorless substance that may be extracted by means of water, but which cannot be changed into the dye by any oxidizing agent. However, hydrochloric acid will transform it into the easily oxidizable leuco-base. One has probably in this case to deal with a transformation product of leucomethylene blue, possibly an acetyl compound of the latter. The author studied the effect of various narcotics of the fatty acid series on the reducing capacity of the organism with reference to methylene blue. The inhalation of ether causes an absence of the dye in the bile and its accumulation in the liver, which fact suggests an inhibition of the biliary secretion; there also occurs a retention of dye in the blood and other organs, as the brain and suprarenal capsules. Chloroform and chloral have the same effects as ether. In poisoning by means of hydrocyanic acid, the brain takes up less methylene blue than the brain of the normal animal. This result, which is quite the opposite to that seen in ether narcosis, is attributed to the diminished affinity of the cerebral cells for methylene blue. This is analogous to the inhibition of the capacity of the brain to take up oxygen, which also occurs in poisoning by hydrocyanic acid. The inhalation of illuminating gas by animals causes the muscles which have been made blue by means of methylene blue, to resume their former color. This result shows that even the moderate and in no way fatal diminution of the oxygen-content of the blood, causes the various organs immediately to satisfy their need for oxygen by the reduction of methylene blue. This is analogous to the reduction of indophenol by the tissues in carbon monoxide poisoning. In order to ascertain the effect of changes in the circulation of the blood upon the reducing activities of the tissues the author injected adrenalin into rabbits which were at the same time receiving methylene blue. As a result the kidneys are nearly or quite unstained. This is ascribed to the effect of adrenalin on the renal vessels. The suprarenals on the other hand take up

more methylene blue than the control animal. This harmonizes with the experience that the suprarenals take up the stain readily if the kidneys are not secreting actively, and *vice versa*, if the kidneys are in active secretion.

PATHOLOGY AND BACTERIOLOGY.

Immunization of Cattle Against Tuberculosis.—That the tubercle bacillus of the turtle is harmless to warm-blooded animals, is the claim made by Friedmann (*Deut. med. Wach.*, November 10, 1904), who reports on a series of experiments undertaken to investigate the possibility of using them as a means of immunizing cattle against the bacilli of Perlsucht. It was found that a single injection of the turtle bacilli produced a degree of immunization sufficient to protect an ox against a dose of Perlsucht bacilli fatal to an untreated animal, and that cattle suffering from Perlsucht are apparently cured by injections of turtle bacilli. The author claims that this method of immunization possesses advantages over others now in use, in that the bacilli employed are perfectly harmless, and that a single injection produces a well-marked degree of immunity. The serum of animals, such as guinea-pigs and cattle, immunized in this way, is strongly protective, and when injected into other animals guards them against otherwise fatal doses of virulent bacilli.

Bacterial Antagonism to Typhoid Bacillus.—A series of highly suggestive researches, which may be of some value in practical medicine, is the discovery by W. D. Frost (*Jour. Infect. Dis.*, November 5, 1904), that mixed cultures of bacteria obtained from the soil and water have a marked antagonism for the typhoid bacillus. This antagonism is displayed when the former are grown in broth and a collodion sac containing the typhoid bacilli is suspended therein. The mixed cultures not merely check the growth of the typhoid germs but kill them. The antagonistic bacteria are widely distributed in nature, and are present in various types of soil and water. The following are examples of these bacteria: *B. vulgatus, B. vulgaris, Ps. fluorescens, Ps. putrida.* Changes in environment, such as temperature, oxygen supply, reaction and amount of dextrose have little or no influence in the production of antagonistic substances. Whenever the environment is such that a good growth occurs, the antagonistic substances are apparently always produced. The energy with which they act depends on temperature. At 38° C. their action is pronounced. At the temperature 10-12° the typhoid germ may be grown in the by-products of the other organisms. The antagonistic substances are thermostable—they withstand a temperature of 120° C. for ten minutes. The cause of the antagonism is not due to an exhausted food supply, action of proteolytic enzymes, specific enzymes or the production of hydroxyl-ions simply.

The Action of Microbes on Foreign Toxins.—Closely related to the subject of bacterial antagonism is the subject of the influence which the growth of certain bacteria has upon the poisons produced by other germs. In this instance one may recall the supposed curative influence which the mixed toxins of the *Bacillus prodigiosus* and the *Bacillus erysipelatosus* have upon certain forms of sarcoma, and the antagonism between certain bacteria of the soil and the typhoid bacillus. Although a different phase of this subject, which is evidently pregnant with much that will be of value in medicine, the investigations of M. Garnier and G. Sabaréann (*Arch. de Méd. Exper. et d'Anat. Path.*, September, 1904), have a peculiar interest of their own. It was Metchnikoff who discovered that some microbes, such as the *Bacillus califorme*, reinforce the toxins produced in bouillon cultures of the tetanus bacillus, while the majority of bacteria, such as the *Bacillus mesentericus, Bacillus subtilis*, and the bacillus of symptomatic anthrax, weaken them. Behring found that the diphtheria toxins can be destroyed by certain microbes. The action of microbes on toxins is variable and depends for its effect upon a broth agent and the thing acted upon. The bacillus of Eberth destroys the toxins of diphtheria, but reinforces the tetanic toxins, at least within certain limits of time. The bacillus of symptomatic anthrax destroys the tetanus toxins but reinforces those of diphtheria. The destruction of the tetanic toxins by the bacillus of symptomatic anthrax is due to a distinct action of the micro-organism upon the toxins and not to any substance excreted by the former. As proof of this fact, it is shown that a filtered culture of the bacilli has no effect upon a mortal dose of the tetanus toxins. A mortal dose, however, is rendered completely benign if it is mixed with the bacilli of symptomatic anthrax and kept in contact with them for fourteen hours. Toxins of tetanus which have become aged, or which have been attenuated by simple contact with the air and light or under the influence of the bacillus of symptomatic anthrax, still preserve a certain toxicity in spite of the complete disappearance of the tetanogenic power. They will thus cause wasting and death in a few days in the animal experimented upon. This is a non-specific property of the tetanus toxins, and is comparable to that which Ehrlich attributes to the toxones produced by a transformation of the specific toxins. The secondary action replaces the primary one. It may also be compared to that which takes place in the organism when poisons lose their specific properties, but still give rise to pathological lesions. As an instance of the latter, the author cites the fact that in old cases of syphilis, parasyphilitic lesions appear which are entirely unlike the earlier manifestations of the disease.

Transudates and Exudates.—As the result of observations in a series of 75 cases, distributed among 12 different diseases, J. L. Miller (*Am. Med.*, November 12, 1903) presents the following conclusions: He claims that the color of the fluid, its reaction and the size of the erythrocytes are of little diagnostic value. Nucleo-albumin is usually more abundant in exudates than in transudates, however, many exudates fail to show more than a faint trace. On account of the constancy of the salts present, the specific gravity and the amount of albumin bear an intimate relation. Fluids from different body cavities of the some individual, or fluids of the same origin in different individuals, or successive tappings of the same cavity, may show marked variation in the amount of albumin, probably explained by the permeability of the capillaries, the degree of irritation of the serous surface, the condition of the patient's blood, the tension of the fluid, the amount of absorption taking place, and possibly the blood pressure. Methods of estimating the bulk of albumin, such as Esbach's and Purdy's, are not applicable to serous fluids. Reuss' formula is the most accurate, simple method for determining the amount of albumin in serous fluids. The diagnostic value of the specific gravity, or amount of albumin, is greatly lessened by the frequent presence, simultaneously, of several processes. A hydremia, as a result of anemia or transudation from pressure, may lower the specific gravity of an inflammatory fluid. Secondary inflammation, high tension of the fluid, or resorption taking place, may increase the specific gravity of

a transudate. At present there is absolutely no reliable method of determining the tuberculous character of serous fluid. The specific gravity of a fluid, when taken for several tappings, may be of prognostic value. The predominence of lymphocytes may be associated with a long standing, simple pleuritis, a hydrothorax or a tuberculous pleuritis. The presence of relatively large numbers of neutrophiles in pleuritic fluids, may be associated with an acute, simple, or a secondary tuberculous pleurisy. The presence of numerous cells, chiefly neutrophiles, suggests an acute simple pleuritis. The presence of numerous lymphocytes with few if any neutrophiles, indicates that the process is probably a tuberculous on. In ascitic fluids there is little that is characteristic. Neutrophiles are usually more abundant in fluids due to portal stasis from cirrhosis than in tuberculous peritonitis. An eosinophilia in one body cavity may occur along with a neutrophilia in another. A study of the cellular elements in fluids from the pleural or abdominal cavities, is of comparatively little diagnostic value, either in differentiating transudates from exudates, or in determining the character of the latter.

The Blood in Measles.—A careful study of the leucocytic changes of the blood in measles has been made by W. TILISTON (*Jour. Infect. Dis.*, November 5, 1904), with the following results: During incubation the leucocytosis begins soon after infection, reaches maximum six days before appearance of eruption and lasts into the first part of the period of invasion. During the latter part of the invasion and during the stage of eruption, the white count is normal or is more usually diminished, reaching its lowest point at the height of the rash. Leucocytoses points to complications, but its absence during the eruptive stage does not exclude complications. The onset of leucocytosis with the latter may be preceded by a rise in the percentage of neutrophiles or a failure on their part to decrease at the proper time. The polymorphonuclear leucocytes are increased during the incubation, invasion and eruption and diminished at defervescence. They are normal during convalescence. Myelocytes are present in small numbers during the eruption, especially in young children. The lymphocytes are at first decreased, and increased after the crisis. The large mononuclears and transition cells are normal at first and increase later. The eosins are decreased or absent in eruptive stage and later increase. The mast cells show no changes. The blood plates are decreased during the eruption. The blood is normal at the twelfth day. In doubtful cases the absence of leucocytosis with a decrease of eosins is in favor of measles as against scarlatina and *vice versa*.

Infective Myositis.—On account of the great circulatory distribution of this rather rare disorder, it is of importance because of its extraordinary virulence. JOHN H. ABRAM (*Lancet*, November 12, 1904) states that out of 17 cases of infectious myositis, referred to by Lorenz, seven were known to have died in from four to sixteen days, while in one of the author's two cases, death occurred on the sixth day. In addition to the well-known classification in Lorenz's monograph on muscle diseases, the author adds the following rather unusual form, to wit: Dermatomyositis. This is not unlike trichinosis, save that the etiology is unknown. After rather vague prodromal symptoms, characterized by marked dermal inflammation, the disorder spreads into the subjacent muscular tissue. There is marked enlargement of the spleen and death is apt to be due to involvement of the respiratory functions. Polymyositis, hemorrhagia very similar to the foregoing, but the heart is particularly involved. Neuromyositis. This affection is very closely related to multiple neuritis. Myositis with joint lesions, acute rheumatism and gonorrhea, myositis tuberculosa,—either hematogenous or due to extension. Myositis-syphilitica,—either a diffuse inflammation with skin implication or gumma. Myositis-fibrosa. May occur as a definite disease, probably due to congenital tendencies, but is more commonly a secondary condition. Myositis-ossificans. (*a*) Local variety practically always traumatic in origin; (*b*) myositis-ossificans progressiva. Affecting children and young adults, associated with inflammatory phenomena and due probably to congenital predisposition. In the suppurative varieties of myositis, it has been shown positively that micro-organisms play a large part in the causation of the disease. In the non-suppurative varieties, however, although the etiology is probably a similar one, nevertheless the relation of the germs has not yet been definitely decided. Bruns' list of muscles in infective myositis is: Pectoralis major, deltoid, triceps and biceps, psoas, quadriceps and gastrocnemius. An important differential point between this disease and ordinary muscular rheumatism is that it is usually accompanied by a moderate degree of temperature. Furthermore, on inspection, the muscles or muscle involved may usually be seen to be shortened and swollen, and on palpation, in many cases nodules may be found in the hardened muscular tissue. If the skin is edematous the detection of these nodules may be very difficult or impossible. Pain, as in other inflammatory conditions, is a marked feature and is very much increased on motion. Furthermore as in other syphilitic conditions, this not infrequently is a marked factor in the syphilitic variety where it occurs only at night. Miyake, in 1904, says that the disease is rather common in Japan, 33 cases having come under his observation in twenty-one months. The disease is clinically met with in three forms: The first being a malignant variety which usually kills within a very few days, the second being an acute form in which recovery is probable, and the third, being a mild subacute form from which recovery is altogether probable.

Experimental Changes in the White Cells.—In a previous article J. ARNETH (*Münch. med. Woch.*, November 8, 1904) stated that in almost all infections, the earlier forms of polynuclear leucocytes, that is, those with single or indented nucleus, predominate, while cells with two and three-lobed nuclei are less numerous. In rabbits, the eosinophile cells take the place of the polynuclears, and if the animals be experimentally infected with various germs or toxins, the same nuclear changes may be observed as in man. Where an animal possessed a natural immunity for some specific toxin, as the rabbit for tuberculin, the changes did not occur, even though the leucocytes of man were affected by the same toxin. The nuclein, which is set free when a polymorphonuclear leucocyte breaks down, is probably of the highest importance for combating infection and it is most probably for this reason that the cells ripen more quickly and constantly receive reinforcements from the bone-marrow. If foreign proteid and other poisons were injected instead of bacteria, the same changes were observed. The red cells also suffer severely if a toxin circulates in the system for normoblasts and even megaloblasts were encountered constantly.

Congenital Hypertrophy of the Heart.—An enormous enlargement of the heart was detected at the autopsy of a child, fourteen months old, by E. HEDINGER (*Virchow's Archiv*, Vol. 178, No. 2). Since the valves and all other organs were free from pathological lesion,

the author was forced to assume that the condition was congenital. The child was perfectly well and developed satisfactorily up to the end of the first year. After that, cough appeared, a pronounced anemia of chloratic type developed, and with the first attempts at walking, the heart became insufficient. An explanation of this condition is very difficult. In other similar cases, the heart was supposed to be the seat of a diffuse myoma, but it is more likely that here some circulatory obstruction existed during intra-uterine life, even though most careful search at autopsy was negative.

First Anatomical Changes in Tuberculosis of the Lungs.—It is difficult to determine what pathological lesions initiate a tuberculosis of the lungs, since the changes are already far advanced in most cases which come to autopsy. Thus A. J. Abrikossoff (*Virchow's Archiv*, Vol. 178, No. 2) found only two cases suitable for study in several hundred autopsies. He concludes as follows: Pulmonary phthisis in adults is generally due to a recent infection with tubercle bacilli and not a result of an exacerbation of a latent process acquired during infancy, as is held by so many. In most cases the lungs themselves are the starting-point of the process; in other words, pulmonary tuberculosis is a primary and independent lesion. The disease begins as a rule in the intralobular bronchi of the apex of one lung, in the form of a productive, tuberculous peribronchitis. Owing to loss of elacticity, as a result of caseation of the primary neoplastic tissue, a circumscribed dilatation of the bronchial lumen will follow. The process spreads from its primary sites in different ways. It travels both in centripetal and centrifugal direction along the bronchus and its branches, giving rise to a tuberculous, peribronchial lymphangitis. The neoplastic tissue surrounding the bronchus, may readily break through the bronchial lumen, both at the primarily and secondarily infected sites and the symptoms of a specific tuberculous bronchitis will soon appear. Cheesy bronchitis and peribronchitis of the intralobular bronchus and its immediate branches, are thus the first stage of the tuberculous lesion. The process may also extend to the abjacent tissue, when it generally retains its productive character and presses together the alveoli of the lung. As soon as cheesy masses have ruptured into the bronchus, an aspiration occurs into peripherally situated areas, and several patches of bronchopneumonia will appear, each one of which corresponds to the terminal end of a bronchus. This may be called the second act of the process. Most recent cases examined were in this bronchopneumonia stage with beginning central caseation as far advanced that an idea of the original structure could only be obtained by staining for elastic fibers. The blood-vessels are not rarely affected by a productive process which surrounds them like a belt and goes hand in hand with a proliferation of the intinia. Vessels of larger caliber are, however, free. The elastic fibers are destroyed late and then in a purely mechanical way. The bronchopneumonia distribution of the initial foci may also be seen in hematogenous miliary tuberculosis and in the experimental tuberculosis of animals; it argues, however, strongly in favor of a primary infection of the lungs in most cases. There can be no doubt that bacilli are often inhaled and the fact that they settle so frequently in the apices is best explained by diminished powers of overcoming an infection here. In children the bronchial nodes are generally affected, first, from the respiratory passages and the lungs are involved secondarily. Bronchial tuberculosis of children has a tendency to remain latent for a long period and encapsulation is never perfect, but with adult age the dangers of propagation become less, owing to calcification and proliferation of connective tissue. At this stage, the bacilli are no longer transported to the glands, but to the lung itself. Secondary involvement of the lungs in children is due to rupture of cheesy material through the walls of the bronchus nearest the node or else by extension of the process into the perivascular lymph-channels of the bronchus. The secondary foci within the lungs do not develop in a typical way, like the primary, unless they spread by way of the bronchi.

PRESCRIPTION HINTS.

Delirium Tremens.—In mild attacks the following combination of hypnotics has proven of invaluable service:

℞ Heroin .....gr. ss (.003)
Veronal .....ʒ iss (6.0)
Elix Sod. Bromid.....q.s.ʒ ii (60.0)

ʒ ss q. 3 hours during day; ʒ ii at night.

And as a stomach tonic in the morning,

℞ Ac. nitro. mur., dil.....ʒ i (4.0)
Tr. cinchon. comp.....q. s. ʒ ii (60.0)

ʒ ii before breakfast.

Moist Eczema.—Such weeping surfaces may be lightly dusted over with oxide of zinc powder, or the following may be applied:

℞ Calamine .....ʒ i (4.0)
Ung. oxidi zinci.....ʒ vii (28.0)

Sig. Apply to spot.

Or the calamine may be applied in a lotion, as follows:

℞ Pulv. calaminæ.....ʒ ii (8.0)
Pulv. oxidi zinci.....ʒ ii (8.0)
Alcoholin .....ʒ ss (15.0)
Aq. rosæ..... ....O i (500.0)

Misce. Apply with cotton.

Flatulency.—The following has been useful in flatuleney and gastric fermentation:

℞ Aquæ chloroformi.....f3 viii (240.00)

Sig. Tablespoonful before and after meals.

Used in chronic gastric catarrh:

℞ Acidi salicylici.....gr. xxiv (1.60)
Oleoresinæ capsici.....gtt. vi (.40)
Strychninæ sulphatis.....gr. ss (.032)
Ext. gentianæ.....gr. xxiv (1.60)

Misce. Fiant pilulæ No. xxiv.

Sig. One after meals.

Hemorrhoids.—Used to relieve painful internal piles with prolapse:

℞ Chloretoni .....gr. xxx (2.00)
Orthoformi .....gr. xxxvii (2.50)
Unguenti belladonnæ.....gr. xxx (2.00)
Iodoformi .....gr. xxx (2.00)
Adipis lanæ hydrosi..q.s. ad ʒ vi (25.00)

Misce et fiat unguentum.

Sig. Apply several times a day.

Mammary Inflammation.—Very useful in acute inflammation with tenseness and of pain. Active saline purge at beginning of treatment.

℞ Unguenti belladonnæ..... ....ʒ i (32.00)
Unguenti hydrargyri.....ʒ iv (16.00)
Ichthyoli.....f3 iv (15.00)
Cerati plumbi subacetatis.....ʒ i (32.00)

Misce.

Sig. Apply to breast freely, and employ tight breast-binder.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, DECEMBER 31, 1904.

A NEW CAPSULAR STAIN.

Among the tasks facing the commission of experts who have undertaken to investigate the cause of the increase of acute respiratory diseases, is that of tracing the conditions of the transmission of the *Diplococcus lanceolatus* from one human being to another. The theory that pneumonia is more or less preventable, rests upon the hypothesis of communicability, and a prerequisite to the demonstration of the mode of communication is the possession of a ready means of differentiating the offending organisms. Biological methods of differentiation have not proven very satisfactory, and the need has been felt of a practical method of morphological identification.

The contribution by Dr. Leo Buerger of a new method for the staining of the capsules of bacteria, promises to be of material assistance in the work above referred to, and is a happy offset to the action of the Civil Service Commission, which, by its ruling prohibiting the employment of non-resident research scholars, threatened materially to impede the progress of the proposed investigation.

By the methods of staining heretofore employed, the encapsulated diplococcus has not been easily and surely distinguished from certain organisms of the streptococcus type. The older stains present the capsule of the diplococcus in the form of a diffusely stained elliptical area immediately surrounding the diplococcus. Dr. Buerger's stain (Medical News, Dec. 10, 1904, page 1117 brings out the capsule in an entirely different manner, presenting a narrow elliptical membrane, deeply stained, which is separated from the diplococcus by a clear interval of capsular substance, which latter area either remains unstained or takes on a faint color.

The type of capsule belonging to the *Diplococcus lanceolatus* is shown by this stain to be entirely different from that characterizing other encapsulated organisms. The method employed appears to depend upon the rapid fixation of the bacteria while still alive and when spread in a medium which prevents dissolution of their capsules.

Dr. Buerger's technical procedure is one of timely interest, and if his method proves as successful in the hands of other workers as in his own, it will undoubtedly be regarded as a distinct improvement upon the methods of staining hitherto in vogue.

MODERN ADVANCES IN ANIMAL ENZYMOLOGY.

Some of the most notable recent advances in the domain of physiological chemistry have reference to the question of enzymology, a chapter which, in animal chemistry at least, was only a few years ago regarded as fairly satisfactorily closed. We had all become acquainted with the ptyalin of the saliva, the pepsin and chymosin of the gastric juice, the trypsin, steapsin and amylopsin of the pancreatic juice, besides the existence of certain indefinite ferments in the enteric juice, the function and origin of which was, however, not very clear. As regards the process of albuminous digestion it was further thought that peptic digestion led to a definite end-product, the amphopeptone of Kühne, in which a hemi- and an anticomplex were still united, while tryptic digestion led to the separation of these groups and the liberation of antipeptone and hemipeptone; the latter, unless directly absorbed, was then supposedly decomposed with the formation of leucin and tyrosin.

In a general way this concept of the process of proteolytic digestion still holds good, but it has been modified and extended in many important particulars. As we have pointed out editorially

some months ago, it has thus been ascertained that Kühne's amphopeptone, as well as his hemipeptone and antipeptone do not represent end-products of proteolytic digestion in the original sense of the term, but that both amphopeptone and antipeptone are mixtures of still simpler products, which in part still give the biuret reaction, while in part they retain none of the original characteristics of the albumins. The existence of a hemipeptone, on the other hand, has thus far only a hypothetical basis. The difference between the process of peptic and tryptic digestion is essentially a quantitative one, in which the element of time plays an important rôle. The end-products are the same and are identical with those which result on hydrolysis of the corresponding albumins by means of acids and alkalies.

The part which pepsin plays during the process of albuminous digestion, has not been materially changed by any of the discoveries of recent years, excepting in so far as the extent of its action is concerned. But in the case of trypsin it has been found that the presence of a special body is necessary before the ferment is capable of exercising its activity. Formerly it was thought that the pancreatic proteolytic ferment existed in the pancreatic cells as an inactive proferment, trypsinogen, which in some manner not definitely understood was transformed into the physiologically active trypsin. It has now been shown that this transformation is effected by a peculiar substance, which has been termed enterokinase, and which apparently belongs to a special class of cellular products, which in themselves are inactive, but are capable of activating certain ferments. Of the mode of action and the chemical nature of enterokinase, we know practically nothing and its origin even has not as yet been definitely ascertained. From the researches of Delezenne, however, it appears that leucocytes (lymphocytes) may be primarily concerned in its production.

Whether or not a kinase is necessary to activate the other digestive ferments of the pancreas also, viz., their proferments, has not been definitely ascertained, but in the case of the fat-splitting ferments at least it seems not improbable.

The secretion of the pancreatic juice was formerly explained upon the basis of a reflex action, in which the acid chyme coming from the stomach represented the stimulus. This conception also has been modified as the result of recent research, for while there is good evidence to show that pancreatic secretion can be reflexly excited, an additional mechanism undoubtedly exists by which the same result can be accomplished. This mechanism depends upon the presence in the circulation of a peculiar body which at first was regarded as a ferment, but which apparently belongs to a special group of products, which have been termed krinins or krinogenic substances, and of which the exponent in the present case is known as secretin. This apparently exists in the epithelial cells of the duodenum and the upper portion of the jejunum and possibly even more widely distributed in the gastro-intestinal canal, in the form of an inactive prosecretin, which is transformed into the active product by contact with dilute acids, etc. It is then absorbed and carried by the blood current to the pancreas, where it exercises its special stimulating activity directly. Of the chemical nature of this substance also we know practically nothing. It is not destroyed by boiling either in acid, alkaline or neutral solution, and can therefore not be an ordinary ferment; is in no way specific of any one animal species, but it appears to be common to and identical in all vertebrates. Whether or not the pancreas is the only digestive gland which is thus stimulated to secretion remains to be seen, but there is some evidence to show that a similar effect can be produced upon the secretion of the bile and the activity of the salivary glands.

To return to our older concept again, it was formerly supposed that the products of gastric and tryptic digestion were reconstructed to native albumins in the gastro-intestinal mucosa, which idea was largely based upon the fact that that "peptones" disappear from their solutions in the presence of particles of intestinal mucous membrane. This observation was placed in a new light by the discovery of Cohnheim that the intestinal mucous membrane contains a proteolytic ferment erepsin, which is capable of hydrolyzing acid albumins and albumoses to the point where the biuret reaction disappears, while it is without effect upon the native albumins. In the experiment mentioned, the "peptones" thus disappear, not because they are reconstructed into albumins by the epithelial cells, but because they are broken down still further. Where and how the reconstruction of the albuminous molecule then takes place after its preliminary cleavage into its ultimate fragments is not known. That it takes place after the epithelial barrier of the gastro-intestinal mucosa has been passed has repeatedly been suggested, but the negative find-

ings in the portal circulation, so far as albumoses and "peptones" are concerned, was regarded as evidence that the process of reconstruction could not occur beyond the intestinal tract. In the light of our present knowledge, however, it is quite conceivable that this may occur nevertheless, but thus far blood analysis for the ultimate products of digestive cleavage has been beset with great difficulties, which, however, are likely before long to fall away. What future studies in this direction will bring is of course impossible to foretell, but it is interesting to note that by the aid of a special method, but recently perfected, encouraging results have already been obtained. So much appears certain in any event that the reconstruction of the albumins takes place through the activity of the body tissues. The question of how of course cannot be definitely answered at the present time; but in view of the rapid progress which is being made in the knowledge of the so-called tissue ferments, and the disclosure of the multitudinous possibilities which here exist, it appears not unlikely that ferment action may also be responsible for albuminous reconstruction. This seems the more likely, as it has been shown that several ferments are capable of reversible action, *i.e.*, both of destruction and of construction.

To enter into a consideration of the intracellular ferments in any detail, however, is out of the question at this place. But it is noteworthy that only seven years ago one of the foremost writers on physiological chemistry in Germany emphatically denied the existence of such ferments. This is the more remarkable as Salkowski had drawn attention to the process of autodigestion of organs some years before, and had insisted that during this process ferments are active which are derived from the tissues themselves. Nevertheless it was maintained that this process, in so far as it could be referable to ferment action at all, was dependent upon what might be termed miscarried gastro-intestinal ferments. The various manifestations of cell life, *i.e.*, the various constructive and destructive changes occurring in the tissues were explained upon the basis of special vital forces, as something distinctive and separate from merely chemical or physical forces. Since that time, however, it has been conclusively demonstrated that not only the phenomena of autolysis, as we see them post mortem in the laboratory, but also many of the catabolic changes occurring during life are referable to fermentation. The ordinary digestive ferments of former days are now very much in the minority, while the tissue ferments are steadily increasing in number. The complexity of ferment action, as we now know it to occur in a single cell, is indeed quite bewildering. In the liver cell, for example, not less than a dozen different ferments have been demonstrated. That the action of some of these is not only destructive, but also constructive, can scarcely be doubted, but as yet our knowledge of ferment action in general is too incomplete to warrant the conclusion that the reversible action which has been demonstrated in some is common to all. Future research in this direction will probably go far to clear up many obscure cellular phenomena, which formerly were attributed to special vital forces.

ECHOES AND NEWS.

NEW YORK.

Appointments at the N. Y. Skin and Cancer Hospital.— Drs. J. Riddle Goffe and Andrew F. Currier have been appointed gynecologists to the above-named hospital, located at Nineteenth Street and Second Avenue. This is the only service in this country exclusively devoted to malignant disease in its preventive, curative and palliative treatment. An open clinic will be held every Tuesday and Friday, from 2 to 4 P.M., when patients will be received. It is especially desired that physicians should recommend and, if possible, accompany their patients.

A Milk Company to Quit.—The milk and cream company whose permit for the sale of its products in New York was recently revoked by the Health Department on account of its insanitary condition, will go out of business, and is now disposing of its stores and property to milk companies which either hold licenses or will apply for them. Dr. Darlington said he thought this was the best move the company could make, as he did not see how he could ever grant them a permit. He said that formaldehyde and coloring matter had been found at the creamery for the adulteration of the milk, and under such circumstances he did not see how the company could guarantee that it would not repeat the practice.

Vanderbilt Ward Open.—Kathleen Vanderbilt, the one-year-old daughter of Mr. and Mrs. Reginald C. Vanderbilt, played the part of Santa Claus, by proxy, to the little sufferers in the Lincoln Hospital, One Hundred and Forty-first Street and the Southern Boulevard, on Christmas morning, when a new ward for children was opened in her name and each one of the inmates got presents from a huge Christmas tree. Recently Mr. Vanderbilt became interested in the institution through the attending surgeon, Dr. Benjamin P. Tilton, and, learning that there was no ward set aside especially for the care of children, decided to establish one. His offer was gratefully accepted, and the Board of Trustees' old room, which is about 50 by 50 was remodeled, at a cost of about $7,000. Twenty beds were put in it.

Columbia Pharmacy Degrees.—The Columbia University Council, at its last meeting, authorized the degree of Graduate in Pharmacy to be conferred, as in the past, by the New York College of Pharmacy at a separate commencement, and provided for the establish-

ment of a course of higher grade leading to the degree of Pharmaceutical Chemist. Candidates for the degree of Pharmaceutical Chemist will be required to pursue a course of study extending over two full academic years. After 1907, the advanced degree of Doctor of Pharmacy, which is now conferred by the College of Pharmacy upon those who hold the degree of Graduate in Pharmacy and who take an advanced course in addition, will be conferred only upon graduates of the advanced course who already hold the degree of Pharmaceutical Chemist.

PHILADELPHIA.

Pathological Society Exhibition.—The annual exhibition meeting of the Pathological Society of Philadelphia will be held on January 11 and 12, 1905, in the Mütter Museum of the College of Physicians. The extension of time will allow of short demonstrations on series of specimens.

Symposium on Food Preservatives.—At the meeting of the Philadelphia County Medical Society, held December 28, Dr. H. W. Wiley, Chief of the Bureau of Chemistry of the United States Department of Agriculture, by invitation gave an address on "Food Preservatives and Food Adulteration." W. W. Smithers, Esq., by invitation, spoke on "Defects in Pennsylvania Food Legislation." Dr. T. L. Coley read a paper on "The Evaluation of Evidence as to the Pharmacologic Action of Food Preservatives."

Street Cars Still Unheated.—The annual talk regarding the Rapid Traction Company because of unheated cars is in progress, and is more pronounced than ever before; the result will probably be the same. Last week there were 76 deaths from pneumonia and many prominent physicians are on record in attributing a proportion of them to the cold cars. Owing to the persistent agitation of the daily papers, mounted policemen have been placed in the most crowded parts of the city to keep the cars moving, but this makes but few minutes difference in time and of course contributes little to the question at issue; it helps traffic which is the only intention.

Merging of Prominent Chemical Firms.—The first of January will mark the merging of two great chemical and drug houses of this city. At that time the manufacturing firms of Powers & Weightman and Rosengarten & Sons, will be united under one supervision. The combination was at the initiative of Mrs. Walker, the daughter and heir of William Weightman. She will be represented in the directorate of the new firm but will take no active part in the management. Business will be conducted as usual at both plants, where nearly one thousand hands are employed. The preparation of morphine and quinine will be almost entirely in the control of the new firm, each of the old ones having a monopoly of one of those drugs.

Effect of Tuberculosis Vaccination Upon Tuberculous Cattle.—At the meeting of the Pathological Society of Philadelphia, held December 22, Drs. Leonard Pearson and S. H. Gilliland, in a paper on this subject, announced experiments which may have an important bearing on the treatment of the disease in question. The experiments began four years ago when from a herd of tuberculous cattle, twelve tuberculous calves were isolated. Of these, six were given injections of tuberculin and human tubercle bacilli and the other six were kept as controls. Some of the calves died and the others were finally killed. Comparison of the lesions showed such difference in favor of the vaccinated animals as to leave essentially no doubt of the beneficial effect of the measures adopted.

Tablet to Dr. Hughes Unveiled.—The bronze mural tablet erected in the Philadelphia Hospital, through subscriptions started by the *Press*, was unveiled on December 27. It is three by six feet in size and is placed in the wall of the main entrance corridor, where it will commemorate Dr. Daniel E. Hughes, who for twelve years was chief resident physician of the institution. He died two years ago from tuberculous peritonitis contracted in the buildings. The tablet bears a life-size bust of Dr. Hughes and the following inscription: "In memory of the self-sacrificing services of Daniel E. Hughes, M.D., Chief Resident Physician of the Philadelphia Hospital from 1890 to 1902. Erected by subscriptions received by the Philadelphia *Press*, from his friends and admirers. Others he helped and saved: himself he spared not. 'A sick man helped by thee shall make thee strong. Thou shalt be served thyself by every sense of service which thou renderest.'"

Improved Health Laws for the State.—At the coming session of the Pennsylvania Legislature will be introduced a bill providing for the reorganization of the public health service of the State. The principal purpose is to prevent the occurrence of epidemics such as happened recently at Butler. The act provides that the State Board shall appoint for each county a practising physician of at least five year's experience to be medical officer of the county; such physicians must have special knowledge of sanitary law and administration. The county courts will name a health officer in each township to serve under the county physician. All these officers will have full power to investigate any thing suspected of being a nuisance, even to pollution of streams, will have authority to make arrests, and may summon witnesses. The idea is to have the state constantly patrolled by a staff of physicians to detect things in any way inimical to the health of the people. The bill has been endorsed by the State Board of Health and by practically all of the medical societies of the State.

CHICAGO.

Smallpox.—Chief Medical Inspector, Dr. Heman Spalding, reports 16 new cases of smallpox sent to the isolation hospital during the week; 15 never had been vaccinated; one had an old, imperfect scar; four were unvaccinated children under the school age. One was an unvaccinated school child in school on a false certificate of vaccination. Four came from the down-town lodging houses. Since January 1, 1904, there have been 323 cases of the disease, of which number 22 died, 251 recovered, and 50 remained in the hospital under treatment.

Children's Hospital Staff.—At a recent meeting of the Board of Directors of the new Children's Memorial Hospital, the following physicians were chosen for the medical staff: Drs. Fernand Henrotin, M. L. Harris, Norman Kerr, J. N. Oswald, Henry G. Anthony, J. W. Class, Hugh T. Patrick, A. M. Hall, Geo. F. Fiske, W. S. Christopher, W. D. Storer, W. W. Quinlan, S. J. Walker, J. P. Houston, and Geo. Chapman. Drs. Frank Billings and Nicholas Senn will act as consulting physicians. A committee of the Board, consisting of Thomas D. Jones, Dr. Samuel J. Walker, E. W. Cramer, W. B. McIlvaine, and James F. Porter has a site for the new building under consideration. Several good pieces of property have been offered, and a selection will soon be made.

Physicians Meet and Plan New County Hospital Staff.—The Commision to nominate members of the County Hospital medical staff met yesterday afternoon, and adopted the report made by its special committee.

It was recommended that a new form of application be printed, so that any physician desiring may apply. It is to be published not later than December 30. Excerpts of the report adopted, with revisions, are: That nervous and mental diseases be established as a separate department of service; that the apportionment of the eclectic and homeopathic members of the staffs in the departments be left to the decision of the representatives of those schools of medicine, and, if they cannot agree, the nominating commission to decide; that all applicants must be citizens of the United States and residents of Cook County for at least five years, and in practice or study for at least five years after graduation; that the following regular departments of service be created, with number of attendants for each as indicated: Surgery, 12; medicine, 12; nervous and mental diseases, 4; diseases of children, 6; obstetrics, 4; skin diseases, 2; diseases of the eye, 2, and diseases of the ear, nose and throat, 2. Seven committees, composed of physicians, were appointed to pass on the applications, one for each department.

Home for Destitute Crippled Children.—The management of this home is making renewed efforts to provide for the necessities of crippled children. Mrs. R. H. McElwee has given the movement a new impetus by donating a dispensary and operating room, but there still remains to be provided, according to present plans, quarters for sixty more unfortunates. The Home accommodates 40, and the plan is for an annex to cost $10,000. In the past year 500 crippled and destitute children have been cared for in the home.

Public Health Conditions.—No material change in public health conditions is indicated by the mortality returns for the week. The death rate continues unusually low for the season. The average December rate between 1893 and 1903 was 15.19 per thousand of population; thus far during the present month (December) the rate has been 13.35, and that for the week is only 13.77, as compared with 15.28 for the corresponding week of last year. The number of deaths from suicide and other forms of violence are the lowest for any week of the year—only a total of 20, as compared with 50 during the previous week, and 51 in the corresponding week a year ago. There is a decrease from the 2,063 hospital patients of the week before to 1,862, although there is a slight increase of pneumonia and typhoid fever cases.

City Lax in Tuberculosis.—"The municipality saves money and spends lives." This is the charge made against the city of Chicago by Samuel Hopkins Adams, who writes on tuberculosis in *McClure's Magazine* for January, 1905. Mr. Adams visited most of the large cities of the country in quest of data concerning the cause, spread and prevention of the great white plague. His investigation in Chicago, he says, demonstrated that the city law-makers have been utterly lax in framing ordinances providing for compulsory registration, whereby the houses occupied by consumptives are reported to the City Hall, and for municipal disinfection and sanitation. "For the type of all that is most inefficient and negligent, we must come back to Chicago," writes Mr. Adams. "Chicago, which in the pride of its civic virtues, stands as the most public-spirited of our great cities! As I have said, there is no compulsory registration law for tuberculosis in Chicago, consequently the authorities know nothing of the foci of infection, excepting in the cases of death, when they get their more or less reliable reports from the physicians, and their usually trustworthy information from the organized undertakers. On such information they send out to the physician a card of inquiry asking whether he considers disinfection of the premises desirable. By replying to this the doctor generally wastes his time—for that's the end of it.

GENERAL.

Women in Medicine.—At the University of Michigan there are at present forty-three women pursuing the study of medicine and surgery, while in the department of law there are only four female students.

Officers of the Southern Surgical and Gynecological Association.—At the last meeting of this Association the following officers were elected for the ensuing year: President, Dr. Lewis C. Bosher, Richmond, Va.; First Vice-President, Dr. John D. S. Davis, Birmingham, Ala.; Second Vice-President, Dr. I. S. Stone, Washington, D. C.; Secretary, Dr. W. D. Haggard, Nashville, Tenn., reelected; Treasurer, Dr. Charles M. Rosser, Dallas, Texas, reelected. Louisville, Kentucky, was selected as the place for holding the next annual meeting, in December, 1905.

No Yellow Fever Epidemic.—Señor Quesada, the Cuban Minister, in view of reports that yellow fever was again obtaining a foothold in Cuba, and that the Cuban Government was not vigorously enforcing sanitary precautions, this week gave out a statement which is in part as follows: "There has been no epidemic of quarantinable diseases. Yellow fever, smallpox, cholera, and the plague have not developed in Cuba since the proclamation of the republic. Neither of the two cases of yellow fever at Punta de Sol in October and November has propagated beyond the original case."

Doctor's Bill, $126,000.—Dr. L. C. H. E. Ziegler, in the Probate Court of Chicago, recently filed a bill of particulars as to claims made by him against the estate of Mrs. Harriet G. McVicker, who died recently in California. Mrs. McVicker was the widow of the theatrical manager, J. H. McVicker. Dr. Ziegler's claim in full amounts to $126,000, the bill including copies of contracts which Ziegler says existed between himself and Mrs. McVicker. The first contract provides that after the death of Mrs. McVicker the sum of $100,000 shall be paid to Dr. Ziegler as soon as possible. This money, according to the contract, was to be given for services as medical adviser.

Levy Tax for Consumptives.—For the maintenance and cure at Denver, Col., of Hebrew consumptives from all parts of the United States a per capita tax is being levied on the members of leading Hebrew benevolent, social and labor organizations. Jacob Marinoff, of the Board of Trustees of the Jewish Consumptives' Relief Society, who has been sent to New York from the headquarters of the national organization at Denver to collect funds for the establishment of a large, permanent sanitarium, said that he is arranging a series of entertainments, concerts and balls to increase the sanitarium fund. The largest of the balls will be held at the Grand Central Palace, on March 9.

Medical Delegates Sail.—Twenty-two physicians left Baltimore on December 27, on board the steamship Athos of the Di Giorgio Steamship Line, bound for Panama. They are delegates from the American Medical Association to the Fourth Pan-American Medical Congress. The party from Baltimore expects to reach Colon on January 3, where they will board a special train for Panama, which Government has appropriated $25,000 for the entertainment of the visitors. The party will be taken back to Colon, and from Colon will sail on January 7 for Havana, where they will be the guests of the American Public Health Association, which meets in Havana on January 9, 1905. The U. S. Public Health and Marine Hospital Service will be

represented at the Pan-American Congress by Surgeons H. R. Carter and J. C. Perry and by Assistant Surgeon C. C. Pierce.

New Charter of the Red Cross.—A new charter of the American National Red Cross has been passed by both houses of Congress, and now needs only the approval of the President to make it operative. This charter, which puts that organization practically under the control of the Government, was drawn by two former Secretaries of State—Mr. Richard Olney and Mr. John W. Foster. Under it the governing body of the general society is to consist of a central committee of eighteen members. Six of these are to be chosen by the incorporators of the parent organization. When six or more State and territorial societies are formed, these will be entitled to elect six members of the central committee, but at present twelve of the eighteen are to be appointed by the President of the United States. When the State organizations are completed, the President will have the appointment of six central committeemen, one of whom he is to designate as chairman. It is provided that the President must select among his committeemen one from each of the Departments of State, War, Navy, Treasury and Justice. From this central committee is to be chosen an executive committee of seven members. In order that the accounts of the organization may be kept straight it is provided that its annual reports must be audited by the War Department, and thence transmitted to congress. By the operation of this provision it is intended to prevent in future such scandals as have grown out of the transactions of the society in the past. The American National Red Cross Society, which the American National Red Cross is to succeed, was organized in 1881, and Miss Clara Barton, the moving spirit in its formation, was for twenty years its chief manager. Its energies were not restricted to war, but some of its most effective work was done in furnishing relief to those suffering from great calamities like the Michigan fire of 1881, the Florida yellow fever epidemic of 1888, the Johnstown flood of 1889, the Russian famine of 1891-92, the South Carolina tidal wave of 1893, the Armenian massacres of 1896, the Galveston tidal wave of 1900, and the Mont Pelée eruption of 1902. During the Spanish-American War the society fitted out ships for the benefit of the soldiers and sailors, but Miss Barton's management of its affairs was the subject of criticism, which, however, was directed at her methods of administration rather than her intentions. The new charter is designed to bring the Red Cross Society into effective cooperation with the Federal Government and its military and civil systems.

OBITUARY.

Dr. G. S. West, died at Palestine, Texas, his home, December 27, of heart failure. He was eighty-one years old, and a well-known Confederate veteran, having been a surgeon of the Sixteenth Alabama Infantry, later a brigadier surgeon and afterward in charge of the hospitals at Atlanta.

Dr. Henry C. McLean, a Brooklyn, N. Y., physician, died last Friday night at his home, 146 Sixth Avenue. He was born in Newburg, N. Y., in 1860, and was graduated from Manhattan College and from the Medical School of the New York University. He started his professional career in Brooklyn and built up a large practice there. He was visiting physician at St. Mary's and Kings County Hospitals, and physician to the Brooklyn Baseball Club. Dr. McLean became a member of the Brooklyn Board of Education in 1886, and served in that body for ten years.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, December 10.

THE TREATMENT OF HABITUAL DRUNKARDS—THE MEDICAL SERVICE OF THE ARMY—MILITARY SURGEONS AND THE MILITARY CLUBS.

The report of Dr. Branthwaite, Government Inspector under the Inebriates Acts, has recently been issued. It deals with three classes of institutions provided for the treatment of habitual drunkards, namely, certified inebriate reformatories; State reformatories, and "retreats." In regard to the first of these classes the following table gives a bird's-eye view of their growth in number and population:

Year.	No. of reformatories.	No. of Beds available.	No. of cases admitted.	Under detention at end of year.	Discharged or otherwise absent.	Total committals at end of year.
1899.	3	227	88	87	1	88
1900.	5	416	144	182	30	232
1901.	6	478	204	288	148	436
1902.	8	624	278	419	295	714
1903.	9	677	298	879	433	1012

From this table it will be seen that at the close of last year there were nine such reformatories in existence. Speaking of them as a whole, Dr. Branthwaite says: "The experience of another year has confirmed many of the opinions formed during the earlier stages of the work, and has resulted in definite advance in many directions." He complains of the difficulties created by the different views taken by judicial authorities of the proper way of dealing with inebriates. Some magistrates object to give what they call a three years' punishment "just for drunkenness." Dr. Branthwaite shows how foolish this objection is, both from the point of view of the inebriate and of the community. He points out that the majority of persons sent to reformatories would, if let alone, spend most of their time in prison. The real object of detention in the case of habitual drunkards is not punishment but reformation. "The community is not," says the Inspector, "in any way protected as long as inebriates, who are a danger to the public or a constant disgrace, are permitted to get drunk every month or so and wreak their vengeance on things in general. The knowledge that no improvement can result from giving longer prison sentences made up of many short periods is definite, and it is certain that intermittent penal treatment, when resorted to, needs to be continued until death or lunacy relieves us of further trouble." In support of this contention Dr. Branthwaite cites what he calls a "sample case." A woman, aged fifty-five years, was committed for two years to a reformatory in June, 1902. The mere enumeration of her previous convictions occupies nine foolscap pages of the report. The first conviction recorded against her occurred in July, 1868. During the interval between that date and June, 1902, she was before the magistrates 315 times. On 284 occasions the charge was "disorderly conduct" or "drunk and disorderly conduct." The "disorderly conduct" was probably in every instance due to the influence of liquor, the charge being stated thus to avoid the necessity of proving drunkenness. As for State reformatories, they, from causes related to public policy, have gradually become places for the care and detention of violent and weak-minded persons, who require for their care and control methods closely analogous to those associated with the detention of the most violent crim-

inals and lunatics. Nevertheless the influence of the State institution is, in Dr. Branthwaite's opinion, one of inestimable value as an agency of reform, for it exists to enable other institutions to do their work in a proper manner, unhampered by the refractory element. "Retreats" are not showing the rapid progress which is evident in the work of reformatories. Their number has not increased during the past year, nor has there been any increase in the number of patients who have been admitted to the existing "retreats." The chief reason of this is doubtless to be found in the fact that entrance to a "retreat" must be the free act of the drinker. Naturally few are willing to surrender their liberty in this way. Since the appearance of the report, Dr. Branthwaite has given evidence as to the law relating to the detention and control of inebriates before a royal commission appointed to consider the question of the care of the feeble-minded. He expressed the opinion that the legal definition of an inebriate should be extended to include persons who bring themselves to the condition of inebriates by the use of other drugs. He further pointed out that under the Habitual Drunkards' Act, 1879, there is no obligation on any authority to provide inebriates' homes, and no power to compel inebriates to enter them. Anyone who can obtain a license from the local authority can open a "retreat" for inebriates, but there are several institutions which are not licensed. Some of these are well conducted, but others are insanitary, overcrowded, badly situated, and have no proper facilities for the employment of the inmates. There are now twenty retreats, in which about 500 persons annually are submitted to detention. That number, according to Branthwaite, is ridiculously small. There are now twelve reformatories, two of which are State institutions. In the "retreats" the average of recoveries is about 30 per cent. In the reformatories, out of a thousand cases, 34 were certified as insane.

In connection with the treatment of habitual drunkards it may be mentioned that the Municipal Council of Glasgow has under consideration a somewhat Draconian method of dealing with such offenders. The proposal is that they should be banished to a lonely island on the west coast of Scotland, there to work out their own salvation removed from the influence of gin-shops. With regard to this proposal Sir Robert Anderson, one of our leading authorities on crime, says that any plan which separates inebriates from opportunities of indulgence is obviously, in the interest alike, of the drunkard and of the community. To some, however, it appears that the transportation of inebriates would be fraught with the danger of horrors such as those which led to the abolition of that form of penalty in the case of criminals.

The Medical Service of the Army is at this moment without an official head. The term of office of the late Director-General, Sir William Taylor, expired on December 1, and there has been a veritable tug-of-war between the military authorities and the Advisory Board which is partly composed of civilian doctors, as to the choice of a successor. The former wish to have a representative of the old order of things; the latter insist on having a man of progressive ideas. The Secretary of State for War, Mr. Arnold-Forster, must have a bad time between the contending parties. He came into office a few months ago with a preconceived policy, the essential feature of which was to undo the work of reform that had been done by his predecessor, Mr. Brodrick. The question whether Mr. Brodrick was or was not a heaven-born War Minister, as his friends declared him to be, need not be discussed here. But there is no doubt whatever that as far as the improvement of the medical service of the Army is concerned, his work was, as far as it went, almost wholly good. Mr. Arnold-Forster's attitude toward the doctors was at first distinctly hostile. The experience gained during his short period of office seems, however, to have taught him that in regard to the medical department, at any rate, it would be a fatal mistake to go back to the old order of things. But the Adjutant-General who, in accordance with the latest scheme of reform, controls the medical service, and who is a staunch upholder of what in Germany is called Junkerism in military administration, has threatened to resign unless he has his way in the appointment of a Director-General of the traditional type. To speak plainly he wants an officer grown grey in the service who may be trusted not to trouble the repose of the War Office by a consuming zeal for the efficiency of his department. The Advisory Board on the other hand are eager to break a tradition which they hold to be largely accountable for the discredit into which the service had fallen at the time of the South African War. They have used all the influence they could bring to bear on the Government to have Deputy Director-General Keogh appointed head of the medical service. Such an appointment would be almost revolutionary, for Keogh is a comparatively young man who was promoted to his present post over the heads of a large number of senior officers. His only disqualification, however, even in the eyes of the military faction, is his youth. It is probable that he will be appointed, as it is understood that Sir Frederick Treves has used all his great influence with the King in his favor, and the Sovereign has—on personal, not on constitutional grounds—a good deal to say in army appointments, if he cares to intervene.

Some years ago it was difficult for a medical officer of the Army to secure election at one or two of the "Service" clubs. At that time a majority of the army doctors were men of rather indifferent breeding from the Scottish and Irish schools, and it must be admitted that many of them were from the social point of view "undesirables." Members of the clubs accordingly conspired together to exclude medical officers, and as a very small proportion of blackballs is sufficient to "pill" a candidate, they generally succeeded. The improved conditions of the service have for a few years past attracted a better class of men in the professional as well as the social sense, and the ill-feeling against the medical branch that used to exist among combatant officers has to a large extent died out. That it still persists in certain quarters, however, is shown by the fact that the other day no fewer than seventeen doctors were rejected in a body at the Junion United Service Club. The incident has excited a good deal of indignation among the members of the club, and it has been ascertained that a clique of retired "fossils" are at the bottom of the affair. The committee of the club has called a general meeting for a day next week when the names of the rejected officers will be submitted for election without the secrecy of the ballot. If the clique persists in its opposition to doctors, the medical members, who number about one hundred and fifty, will organize themselves into a clique which will systematically blackball every candidate proposed for election, to whatever branch of the Army or Navy he may belong.

THE EXPERIMENTS OF L. LIEBERMANN.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In an editorial published in your issue of December 24, you refer to the recent labors of L. Liebermann in the following terms: "The experiments

of L. Liebermann on colloidal platinum also opens a vast field of possibility in the domain of pathology. This observer states that the mechanism of the oxidative reaction helps to explain certain phenomena connected with the destruction of foreign and toxic bodies in the organism. Certain pathogenic bacteria are rendered innocuous by uniting with protective bodies normally present in the organism, the complements of Ehrlich. But these act so slowly that they cannot fortify the organism against an intoxication. On this account another body is necessary, the amboceptor (immune body), which will unfold the activity of the complement. The analogy to the phenomena of the oxidative reaction is as follows: The pathogenic agent corresponds to the tissue, the complement to the active oxygen, and the amboceptor to the oxidase. The amboceptor is thus nothing more than a catalyzer."

I wish to call your attention to the fact that Liebermann's conclusions only confirm those submitted by myself two years ago, in the first volume of my work on the "Internal Secretions, etc." The most casual perusal of this volume will show that the 800 pages it contains serve mainly to emphasize the overwhelming importance in physiology, *pathology* and therapeutics, of the oxidizing substance, the so-called "oxidases" of the blood. Not only is their rôle in each organ, including the nervous system, defined, but their identity (the secretion of the adrenals, which, by taking up oxygen in the lungs, becomes my "adren*oxin*") is also given. The complement of Ehrlich is assimilated therein, owing to its physicochemical attributes, to a trypsin-like body in the blood-stream. This body, in order to become effectively bactericidal or antitoxic, is stated by me to require the aid of adrenoxin —also said, owing to its properties, to correspond with Ehrlich's amboceptor or immune body. I likewise specify that adrenoxin only produces its effects indirectly, *i.e.*, by catalysis, its rôle being to combine with a third body, fibrinogen, in order to enhance through the effects of an exothermic reaction, the proteolytic activity of trypsin, which activity as is well known, steadily increases under the influence of heat, up to a given limit.

Very truly yours,

CHARLES E. DE M. SAJOUS.

Philadelphia, December 26, 1904.

SOCIETY PROCEEDINGS.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, held at Birmingham, Alabama, December 13, 14 and 15, 1904.

The Association met in the Council Chamber of the City Hall, and, in the absence of the President, Dr. Floyd W. McRae, of Atlanta, Ga,. the Second Vice-President, Dr. J. Shelton Horsley, of Richmond, Va., presided.

Addresses of Welcome were delivered by Mayor Drennan and Dr. L. G. Woodson, which were responded to by Dr. W. P. Nicolson, of Atlanta, Ga.

After a brief report from Dr. John D. S. Davis, Chairman of the Local Committee of Arrangements, relative to entertainments, order of procedure, etc., the reading of papers was proceeded with.

Method of Uniting Intestines of Very Small or of Unequal Caliber.—Dr. J. Shelton Horsley, of Richmond, Va., said that there were many modifications of sutures, but all of them might be divided into two general classes, the continuous and the interrupted. Taking it for granted that each suture penetrated all coats of the intestines, he demonstrated experimentally that the continuous suture more nearly fulfilled the ideal conditions for intestinal healing than the interrupted suture. Serous surfaces united after being sutured on account of the hyperemia of repair, and this was dependent upon some slight injury to the peritoneum. In the case of an interrupted suture, union was obtained within the bite of the suture by hyperemia caused by pressure of the suture, by the trauma of the needle, and by the presence of the thread. Between the sutures the pressure from thin intestinal tissues was practically *nil*, so union depended solely upon extension of this hyperemia, and if this process did not extend from one stitch to another, leakage would surely occur. If continuous and moderate pressure was made on two serous surfaces, sufficient injury would be done those surfaces to cause adhesions. This continuous pressure along the entire margin of an intestinal wound could be obtained only by the continuous suture, and not by the interrupted. He described nine experiments in which an area of intestine was included between two lines of sutures. In only four of these did the whole area between the rows of sutures unite, demonstrating that something besides mere approximation of serous surfaces was necessary for satisfactory union. The method of suture was difficult to describe without accompanying illustrations. The intestinal ends to be united were placed side by side with their convex borders in contact and clamped with a hemostatic forceps. Then he used a suture that passed through the whole of the intestinal wall, sewing together with a continuous stitch a crescentic area excised; then changing the stitch to a Cushing right-angled continuous suture penetrating all the coats and invaginating the remaining margins of the wound. When the first knot was reached in the suture, it was invaginated and the suture continued by two or more insertions of the needle; with the last two insertions of the needle, as secure a hold as possible was obtained without penetrating the mucosa. The very last insertion of the needle was in the reverse direction of the other insertions so that when the knot was tied it was partly buried. The bowel was then returned to its natural position, and the mesentery sewed up with continuous stitches. A number of photographs and specimens from dogs were exhibited, demonstrating some of the advantages claimed for this method. These specimens had been filled with paraffin and then photographed; afterwards the intestine was removed, and the paraffin model was also photographed, giving a very good idea of the large lumen at the site of the union.

Dr. W. P. Carr, of Washington, D. C., stated that the holding of the bowel with a clamp, a rubber ligature, tape, or something of that sort, to prevent the escape of intestinal contents during operation was the only part of intestinal suture that seemed not to be as perfect as it might be. There was more or less danger of injuring the bowel by any sort of clamp or ligature which was put around it tight enough to prevent the intestinal contents from escaping. The Murphy button or any form of clamp might possibly do that at times, particularly if the bowel was already more or less inflamed at the time of the operation. He thought it was better to hold the bowel with the fingers of an assistant when this was possible, although it facilitated the operation very much to take the bowel in a long clamp not far from the point where it was going to be sutured, as it prevented the sliding of the coats of the bowel over each other.

Dr. Herman J. Boldt, of New York, personally preferred suturing to using buttons or mechanical devices for the purpose of intestinal anastomosis.

Lateral Anastomosis.—Dr. J. M. T. Finney, of Baltimore, Md., said that in his experience he found that there were certain technical difficulties to the end-to-end suture which were hard to overcome. For instance, at the mesenteric border it was difficult to obtain satisfactory union; there was so much likelihood that a leak would occur there, that it had been his practice for the last two years to use almost exclusively lateral anastomosis, closing both ends. This gave more satisfactory union. He was an advocate of the interrupted suture.

Continuous Suture.—Dr. A. Palmer Dudley, of New York, stated that in his experience the use of the continuous as against the interrupted suture had been followed by fairly good results in intestinal work.

Dr. W. S. Goldsmith, of Atlanta, stated that in placing continuous sutures around the bowel, where there was likely to be distention, leakage might result, and a fistula be produced by tissue necrosis incident to the distention of the bowel on account of the application of this ligature. It was a ligature in effect around the bowel; we had distention of the gut, and the ligature did not expand; there was no elasticity about it. Therefore, the interrupted suture would be his preference, although not so rapid, minimizing the pressure owing to distention or dilatation of the gut.

Dr. Samuel J. Mixter, of Boston, said that where one was in a hurry the continuous suture was quicker. He emphasized the absolute necessity of everybody practising these operations on lower animals before beginning to do them on patients. This was a point that was not sufficiently recognized. Every new method should be tried on some of the lower animals. So far as his experience went, very little clamping was necessary even if there was some leakage. He did not consider that there was any great danger from septic peritonitis following, because the peritoneum was able to stand a great deal of soiling without great damage, and it could be washed off without producing any ill-effect. This was likewise true of operations on the stomach.

Intestinal Obstruction.—Dr. Dyer F. Talley, of Birmingham, Ala., said that the subject of intestinal obstruction was one which could not be too frequently presented to the profession, and one with which it could never become too familiar. It was a condition which presented many difficulties in its early diagnosis, and it was a well-recognized fact that in acute cases the life of the patient depended on early recognition and prompt surgical intervention. There were two difficulties in the way of early operation: (1) It was hard to make a positive diagnosis in the first twenty-four hours; indeed, in some cases it was impossible to do so unless an exploratory laparotomy was made. (2) There was a tendency on the part of the patient, his friends, and also the physician, to wait until tomorrow and see what purgatives and enemata would accomplish. The author reported eight cases of intestinal obstruction that had come under his care during the last fifteen months. The details of each case were recounted with singular clearness. One case showed that a laparotomy could be done without anesthesia, and many cases that were seen late and were too weak for an anesthetic might be operated on and relieved without a general anesthetic. The results of operations in the eight cases were five recoveries and three deaths.

Dr. Guy Leroy Hunner, of Baltimore, stated that from a large experience with hospital and private patients showing symptoms of intestinal obstruction, he had come to the conclusion that he would rather err on the side of operating occasionally unnecessarily than to commit the error of not interfering and be too late. Cases were cited in point.

Dr. W. P. Carr said the more he saw of cases of intestinal obstruction, the more he was convinced that whenever there was a strong suspicion of it an exploratory operation should be made. There were so many cases that had little or no symptoms for quite a while, and others that had considerable fecal movements from the lower bowel after obstruction had taken place, that one was apt to be misled. He had been misled a number of times. He narrated some interesting cases.

Early Operation.—Dr. J. Garland Sherrill, of Louisville, Ky., advocated early operation in these cases. Whenever a patient had intra-abdominal pain which was not promptly relieved, an exploration should be made. Whenever a patient had a severe pain in the abdomen that ceased suddenly, it is likely to be the result of gangrene of the gut, and for that reason such a case should demand very prompt operation. Many of these patients could be saved by opening the abdomen at once, even in the presence of shock, and in that way avoid inflammation of the peritoneum.

Dr. Chas. L. Bonifield, of Cincinnati O., recommended changing to ether when patients could not stand chloroform, particularly in children.

Laparotomy in Intussusception.—Dr. W. O. Roberts, of Louisville, Ky., narrated the case of a child, nine months old, on which he had operated. The little patient had been treated for dysentery. When he saw the patient there was a considerable amount of distention, great straining, and bloody mucus passed by the bowel. He introduced his finger into the rectum, and found an intussusception. The intussusception was within two inches of the anus. He advised laparotomy, which was consented to and performed, and found the intussusception began at the ileocecal opening, and went clear to within two inches of the anus. It was relieved very easily; but the child died in the course of twelve hours from shock. It was very important in all cases of intestinal obstruction to examine the rectum carefully.

Early Diagnosis.—Dr. Wm. E. Parker, of Hot Springs Ark., said the general practitioner ought to be impressed with the importance of early diagnosis in these cases, and if there was any question at all to call in a general surgeon, or someone who had had experience in this class of cases. He knew of no class of work in which an early diagnosis was as important, and then after this of getting into and out of the belly as quickly as was consistent with good work.

Dr. W. P. Nicolson, of Atlanta, Ga., called attention to the significance of abdominal pain. One should always bear in mind that the location of pain in the abdomen bore practically no relation to the location of the lesion itself in many instances. When a patient, with a severe abdominal pain, was not relieved by two or three doses of morphine, and did not remain relieved by this agent, but needed a repetition of it, the case was not one of indigestion. It was far more serious. He had the misfortune to operate on a young woman for intestinal obstruction, and during the operation there was tremendous fecal vomiting, which was aspirated into the lungs—some of it. She left the table in good condition, with good pulse, and with indications that she was all right; but within a short time she became cyanosed, with rapid breathing, pulse increased in rapidity, and remained conscious, but died within two hours.

Gangrene Following Intussusception.—Dr. Samuel J. Mixter said that given a patient who had had intestinal obstruction for days, and was in a very critical condition, he thought many of them could be saved if too much was not attempted, and the reason so many of these patients died was because surgeons attempted too much. Take a case of gangrene following intussusception, if a simple opening was made in the most distended

loop of bowel, a tube tied in and the intestine drained, a later operation could be done, and the patient probably saved, whereas if one attempted to do a resection or a serious operation at the time, the patient would surely die.

Morphine Masks Symptoms.—Dr. A. Palmer Dudley said that the surgeon was at a great disadvantage when he was called in to see a patient to whom morphine had been administered for the relief of pain, for the reason that it masked the symptoms. Peristalsis was arrested and the obstruction went on more rapidly. He had not given a dose of morphine in fifteen years to any patient on whom he had performed an abdominal section.

Dr. Talley, in closing, said the principal point he wanted to emphasize was the importance of early operation, because he believed that most of the patients could be saved if reached and operated upon early enough.

Review of One Thousand Operations for Gall-Stone Disease, with Especial Reference to the Mortality.—This was the title of a joint paper by Drs. William J. and Charles H. Mayo, of Rochester, Minn. The paper was read by Dr. Chas. H. Mayo, In one thousand operations for gall-stone disease there were 50 deaths—five per cent.—counting as a death every patient operated upon who died in the hospital without regard to cause of death or length of time thereafter; 960 for benign disease, with 4.2 per cent. mortality. More than one procedure through a single incision, only the major was counted, therefore 101 cholecystostomies, and 44 cholecystectomies in connection with common duct operations were not included. Of 673 cases operated upon by cholecystostomy there was a mortality of 2.4 per cent. This group included most of the acute infections. In no case did the stones reform in the gall-bladder. This was the operation of choice in the average uncomplicated case, and especially if there was or had been cholangitis. Of cholecystectomy, there were 186 operations, with a mortality of 4.3 per cent. This operation was employed for special indications, such as cystic duct obstruction, thick-walled gall-bladders suspicious of malignant disease, and cholecystitis without calculi. There were 137 operations for stone in the common duct, with a mortality of 11 per cent., 7 per cent. from the operation, and 4 per cent from secondary complications after more than three weeks. Of the cases operated upon during the quiescent period, with little jaundice and slight infection, all recovered. There were four cases with extreme icterus from obstruction, who had subcutaneous hemorrhages at the time of operation (purpura). All of these died; four cases of complete biliary obstruction in which the common and hepatic ducts were filled with clear cystic fluid and no bile, all died. Including malignant disease, 14.6 per cent. of the total were of the common duct; 40 cases of malignant disease, with 22.5 per cent. mortality; two cases with cancer of the gall-bladder now alive and well more than two years after operation; two additional favorable cases of more recent date. Of the remaining malignant cases, a few received marked palliation, but the majority were but little benefited.

Enterostomy.—Dr. J. W. Long, of Greensboro, N. C., stated that the important measures to be accomplished were, (1) the drainage of gas and feces from the intestine. (2) In mechanical obstruction, relief of distention, pain, vomiting, and toxemia (3) In septic conditions depletion of the inflamed bowel and peritoneum, overcoming intestinal paralysis and sepsis. (4) Protection of the peritoneum as in typhoid perforation. (5) Nourishment of the patient by making an artificial mouth. Enterostomy was employed only in the most desperate cases and in those where it was indicated the patient is always in imminent peril of speedy dissolution from some of the conditions above indicated. In all forms of intestinal obstruction the patient suffered from distention and absorption of the toxins. When septic peritonitis was present, the sepsis itself produced suspenion of peristalsis, which was sufficient to account for the obstruction. In mechanical obstruction, to this factor was added painful peristalsis. In recent years enterostomy had been applied to a number of conditions other than intestinal obstruction *per se*, the principal indication being feeding the patient through the fecal fistula. This operation had been applied to cases of inoperable carcinoma of the stomach, a fistula being made in the jejunum and the patient fed through it; life prolonged, and the patient made more comfortable. Enterostomy was also to be applied to typhoid perforation, catching up the perforated bowel and fastening it to the wound, it being more quickly done than closure of the perforation; at the same time, the bowel was drained and the patient fed through the fistula. Dr. Long reported eight cases of enterostomy occurring in his practice in twenty-two years, with five recoveries or 62½ per cent. He drew the following conclusions: "(1) Enterostomy is a life-saving measure and never an operation of choice. (2) Enterostomy is not indicated where a more ideal surgical procedure is feasible. (3) In the hands of an experienced, carefully trained, competent surgeon, capable of dealing with grave emergencies, enterostomy need rarely be resorted to, but the better the surgeon, the more quickly he will adopt any measure which will rescue his patient. (4) Every abdominal surgeon must, according to the abundance of his material, find cases in which only enterostomy can with propriety be done. (5) When an enterostomy is indicated, to hesitate is to lose the patient; to operate promptly, dextrously, and with celerity means to tide the patient over the imminent peril and spare him for future consideration."

Drain the Intestine.—Dr. James A. Goggans, of Alexander City, Ala., said that drainage of the distended intestines was very important. He made it a rule, if possible, when he did a laparotomy for any trouble whatever, to drain the intestine in order to let it regain its elasticity and move the fecal current along as it should. He commended the author of the paper for advocating enterostomy and draining where the intestine was greatly distended in the class of cases under consideration.

Dr. J. Garland Sherrill said that enterostomy had a place in surgery in those cases where complete surgery could not be done; but whenever a surgeon sent a patient away from the operating table with an open intestine, he subjected the profession and himself to criticism from the laymen who did not understand the condition. Therefore, he would lay it down as a rule that no enterostomy should be done in any case where it was possible to do complete surgery, and instead of widening the field for enterostomy surgeons should strive to contract it.

Dr. J. S. Stone, of Washington, D. C., said the essayist must have gotten hold of a number of very difficult and delayed cases for operation. He thought the idea of the essayist was simply this,

that rather than let a patient die from obstruction, he would catch up a loop of bowel and make an artificial anus. This was the old-fashioned way of doing enterostomy, and the essayist got as good a mortality as most surgeons would have gotten under the same circumstances. Dr. Long, in closing, said it would seem that he had unfortunately ran afoul of quite a number of cases in which it seemed proper to do enterostomy. These eight cases were spread over a period of more than twenty-two years of practice. He doubted if any surgeon had a better percentage of recoveries in cases of acute intestinal obstruction by any method than that which he had reported, namely, 62½ per cent.

Abuse of Purgatives Before and After Abdominal Section.—Dr. I. S. Stone, of Washington, D. C., read a paper with this title in which he said that purgatives should be given as evacuants, and should not produce hypercatharsis, whether administered before or after abdominal section. Bland evacuants, such as castor oil, aided by suitable enemata, would empty the bowels without causing severe exhaustion. The writer agreed with Ochsner's method. The excessive purgation, hypercatharsis, commonly employed, was intended not only to empty the bowels, but to perform additional service, namely, to remove collections of serum or other fluids which might be in the peritoneal cavity. A large majority of the sections made at the present time might be called minor pelvic or abdominal. In these no infection existed, nor was the intestine in any way involved. Such cases required only the mildest evacuants, with sterile diet in the preliminary treatment. He deplored the extreme and unnecessary purgation to which these patients were frequently subjected. If the minor abdominal cases were not in need of hypercatharsis, one might next consider how consistent was this rigorous catharsis in very ill patients. Vomiting, paresis, ileus, and excessive distention after operation were frequently exaggerated and aggravated by the administration of the worse than useless cathartics which were usually given. No remedy had been discovered for vomiting due to anesthesia, and this fact should interdict the annoyance given patients by using purgatives before normal peristalsis had been restored. The only remedy of value for vomiting was the regulation of stomach contents, both as to character and quality of substances ingested. The stomach tube was therefore an instrument of great value, if one had need to reach and treat this viscus, with a view of obtaining rest and relief of distressing emesis. It had been shown that patients had bowel movements (peristaltic) after surgical operations, because they were ready to act rather than because one had found any method to produce such results. Hypercatharsis did more than anything short of venesection, or the use of dangerous heart depressents, to unfit patients for prolonged anesthesia and operation. The prompt administration of purgatives after operation appeared to cause vomiting and reversed peristalsis, and to add to the general discomfort of the patient. The temporary paralysis of the intestines in nearly every case was to be desired, and nearly all patients having been properly prepared would recover far more satisfactorily with perfect rest until normal peristalsis returned, than with the aid of all sorts and kinds of irritants intended to produce quick movements of the bowel. If the intestines were not actually scoured by catharsis and had only been fairly well emptied of excess of gas and fecal matter, they would respond to treatment after operation with far greater ease than when made absolutely empty.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904,

SECTION ON LARYNGOLOGY AND OTOLOGY.

(Continued from Page 1200.)

The Treatment of Non-Suppurative Disease of the Middle Ear.—Dr. Urban Pritchard, of King's College Hospital, said the treatment of non-suppurative disease of the middle ear is, with certain exceptions, very unsatisfactory. The classification of the conditions included under non-suppurative disease of the middle ear is not yet agreed upon, but for discussion of treatment the following rough divisions will suffice: (1) Acute non-suppurative otitis media. (2) Early stages of chronic non-suppurative catarrh. (3) Advanced stages of the same. (4) Middle ear adhesions, the result of former acute inflammation. (5) Sclerosis resulting from disease of the bony capsule enclosing the internal ear, and forming the inner wall of the tympanic cavity, and this is not a catarrh at all.

Treatment of Non-Suppurative Acute Otitis Media.—Teach mothers to put a mustard leaf behind the ear instead of a septic onion and such like into the external meatus, and then fewer would run on to suppuration. In the earliest stages, gentle, not forcible, politzerization (not catheterization) will often relieve the pain at once, and tend to cut short the attack. Counter-irritation behind the ear is always most valuable, and will often arrest the otitis and relieve the pain. Instillations are only occasionally advisable; when used, should be strong anodyne solutions—for example, cocaine or morphine—in an antiseptic medium. Glycer. acid carbol. has been strongly recommended; also adrenalin with cocaine, but he does not think them of much service. Heat in the form of very hot fomentations, or hot bran bags, is very useful. Leeches in front and below the ear are valuable in very acute cases. Incision of the membrane is called for when there is marked bulging of the membrane. The meatus must be purified and afterward dressed antiseptically to avoid suppuration. Purgatives are nearly always necessary. Phenacetin or antipyrin, etc., may be given to relieve the pain. Pharyngeal treatment is usually required, but nasal douches or irrigations must absolutely be avoided. Politzerization should always be employed; will restore the hearing and prevent adhesions. If adenoids are present they must be removed.

Treatment of Advanced Stages of Chronic Middle-Ear Catarrh.—This is much less satisfactory, on account of the adhesions causing retraction of the membrane and fixation of the membrane and ossicles. Catheterization is often preferable to politzerization, but the value of courses of repeated inflations has been much overrated. Patients must be warned against the constant recourse to Valsalva's method of inflation; at the same time, cautiously employed it is of value. Gentle suction by means of Delstanche's masseur is occasionally of value, but may easily be overdone. We have yet to learn the value of the rapid suction massage recently introduced. The Eustachian bougie has been overrated. The objections to its use are: First, the risk of injury to the delicate ciliated mucous membrane; the narrow part of the tube being bony, it cannot be dilated except at the expense of this mucous membrane;

secondly, in advanced cases the loss of hearing power is almost always due to changes in the tympanic cavity and not in the Eustachian tube. Nasal irrigations of sterile alkaline and saline solutions are of much value. Inhalations of the ammonium chloride fumes, with cautious Valsalva's inflation to introduce them through the Eustachian tubes, form a most valuable treatment, but long-continued use, with intervals of rest, is necessary. Injections through the Eustachian catheter are much employed by some surgeons, and are occasionally of value; probably a sterile solution of sodium bicarbonate is the most efficacious. Occasionally, when the mucous membrane is glazed and dry, small doses of potassium iodide with ammonia, so as to produce slight symptoms of coryza, combined with some form of inflation, will yield excellent results. Turkish baths are of value in some of the less advanced cases.

Hard Paraffin in Nose Deformities.—Dr. Walker Downie, of Glasgow, spoke of his experience in 100 patients, in the past two and one half years and concludes: That the operation of the subcutaneous injection of paraffin to raise a sunken nose, if properly performed, is practically devoid of danger. Further, where the deformity is of the nature of a sinking-in, and where the skin covering the sunken area is healthy, the shape of the nose can in all cases be improved, and in most the deformity can be by this means wholly removed. This operation, by modifying or removing a disfiguring and prominent deformity, is the means of conveying much comfort to the individual operated upon.

Section on Medicine.

A Disseminated Form of Croupous Pneumonia in Children, or Primary Bronchopneumonia.—Dr. Samuel West, of London, drew attention to the fact that acute pneumococcal inflammation in the child often occurs in a disseminated form. Acute inflammation of the lung presents itself in two forms: in the one as a massive consolidation, in the other as disseminated patches. The massive consolidation is the type in the adult; it often comes on without previous illness or obvious cause, and is therefore called idiopathic or primary. The patchy or disseminated form is the type in the child. It usually follows bronchitis, and is therefore called secondary consecutive pneumonia, or more commonly bronchopneumonia. Massive consolidation is rarely met with in children. At St. Bartholomew's Hospital, during a period of ten years, there were admitted 412 cases of bronchopneumonia, of which 82 per cent. were under five years of age. During the same period, 1,786 cases of lobar pneumonia were admitted, of whom only 14 per cent. were under the age of five years, the relative frequency of bronchopneumonia at this age-period being as 6 to 1. The description usually given of bronchopneumonia in children would lead to the conclusion that it was rare, except as the result of bronchitis. Yet this is not so. On the contrary, a considerable number of the cases occur without antecedent bronchitis, begin and end just like the acute pneumonia of the adult, and might be regarded as such, except that during life the physical signs show, and in fatal cases the post-mortem examination demonstrate, not massive consolidation, but disseminated patches.

Bacteriological evidence, then, so far as it goes, shows that in the primary cases of bronchopneumonia the pneumococcus is almost as frequently found as it is in the acute pneumonia of the adult, and thus confirms the conclusion to which clinical observation leads—that primary bronchopneumonia is of pneumococcal origin. It seems, therefore, fair to draw the following conclusions: (1) That the primary and secondary bronchopneumonia have a different bacteriology. (2) That primary bronchopneumonia, is of pneumococcal origin. (3) That pneumococcal inflammation is almost as common in the child as in the adult. (4) That it takes a different form in each, usually leading to massive consolidation in the adult but to disseminated patches in the child. In other words, lobar pneumonia and primary bronchopneumonia are the same disease. There are many peculiarities of structure in the child's lung which seem adequate to explain why inflammation of the lung in a child should take a different form from that which it presents in the adult.

Human and Bovine Tuberculosis.—Dr. Nathan Rau reiterated the theory which he put forward twelve months ago at the British Medical Association in Swansea, and which he believes is thus supported by eminent authority, namely, that the human body is affected by two varieties of tubercle, one producing phthisis pulmonalis, and generally attacking adults; the other bovine tuberculosis, attacking children during the milk-drinking period and producing bovine tuberculosis in children. In his original paper he expressed the opinion that these two diseases were antagonistic to each other in the human body, and that children who have suffered from bovine tuberculosis in the form of strumous glands, spinal disease, strumous joints, etc., did not develop true phthisis pulmonalis in later life—in fact, he argued that this mild bovine infection conferred a certain immunity against phthisis in the same way as vaccination and smallpox. This theory has also received great support by the work of Dr. Römer, of Marburg, who has been endeavoring to immunize cattle against tubercle. The only strain of tubercle bacilli which he finds produces complete immunity is the human strain, and by using human bacilli he has been able to immunize over 1,000 cattle, not one of which has contracted tubercle, although repeatedly exposed to infection by living in the same stalls with infected cattle. If human bacilli will protect cattle, it is natural to suppose the converse—that bovine tubercle in children will protect them against human tubercle or phthisis. He concluded by expressing the opinion, based almost exclusively on clinical and pathological evidence, that human and bovine tuberculosis are separate and distinct varieties of disease, as shown by Professor Koch; but that the human body is susceptible to both, and especially to bovine tuberculosis in the early periods of life. The two diseases are so rarely seen together in the human that there seems to be some ground for presuming that they are antagonistic to each other, and that bovine tuberculosis may possibly confer an immunity against human tuberculosis. If this opinion should prove correct, he ventures to submit that it would reconcile the conflicting opinions which have been so frequently expressed during the last two years on this most terrible of all diseases.

Heart Disease in Pregnancy.—Dr. J. Mackenzie, of Burnley, discussed this topic, showing many charts and diagrams. In regard to the question of pregnancy occurring in women with valvular disease, the following conclusions may be drawn from this study: (1) When there is a distinct evidence of failure of compensation, or when the patient is liable to frequent attacks of failure of compensation, pregnancy should be forbidden. (2) With fair compensation, if there should be paralysis of the auricle, as evidenced by the presence of a diastolic murmur and the absence of a presystolic murmur, or of a continued irregularity of the pulse, or of a jugular pulse of the ven-

tricular type, pregnancy should be forbidden. (3) With fair compensation, with a mitral murmur systolic or presystolic in time, with the apex beat within the nipple line, and due to the left ventricle, the patient may undertake the burden of pregnancy. In all cases of valvular disease, when conception has taken place, the patient should be kept under close observation. One feature of great prognostic significance is the presence or absence of symptoms of edema of the lungs.

Role of the Lymphocyte.—Dr. G. Lovell Gulland, of Edinburgh, opened a discussion on this subject, taking up the question of the Nature, Relations, Origin, and Function of Lymphocytes. The first question which it is desirable that should be answered with some approach to unanimity is, What is a lymphocyte? Of the so-called non-granular cells of the blood most authors, following Ehrlich, distinguish four varieties: Small lymphocytes, large lymphocytes, large mononuclears, and transitional cells. There is a general agreement that the small and large lymphocytes are identical, the small being the younger form. Ehrlich says that the mononuclears are to be strictly separated from the lymphocytes, and that this separation is "founded on the fact that they differ entirely in their whole appearance from the other type, and that transitional forms between them are not to be observed." He defines them as cells two or three times the size of a red corpuscle, with a large oval, and generally eccentric nucleus, staining rather feebly, and with a relatively large amount of protoplasm free from granules, weakly basophile, and, in contradistinction to the lymphocytes, less basophile than the nucleus. They become transformed in the blood (according to Ehrlich) into the transitionals, which are to be distinguished from them by the possession of a more or less horseshoe shaped nucleus, which has a rather greater affinity for stains, and by the appearance of a few neutrophile granules in the cytoplasm. These cells are supposed to be transitional between the large mononuclears and the polymorphonuclear neutrophiles. Gulland's own view is that the lymphocytes, mononuclears, and transitionals are merely stages in the development of one type, and that there is no relation between the transitionals and the polymorphs. There are four assigned reasons for the distinction between lymphocytes and mononuclears and transitionals: (1) The cytoplasm of the latter is not so basophile. (2) The nucleus is relatively smaller in the case of the mononuclears, and differently shaped in the case of the transitionals. (3) The presence of granules in the transitionals. (4) The larger size of both sets of cells.

1. The cytoplasm of the larger cells is not so basophile, simply because there is more of it and the basophile parts of it are less crowded together. All the members of the group have a cytoplasm, of which the ground is very faintly basophile, and in all four members the depth of tint which this assumes is much the same. The strands and nodes of the cytoplasmic reticulum which traverse this ground substance vary a great deal in thickness and in closeness of apposition, not only in different cells, but in different parts of the same cell. The thicker the strands and the more closely they are apposed the more basophile do the cells appear to be. Thus, in small lymphocytes in which the strands are short and densely crowded together, the cytoplasm looks almost homogeneously basophile to superficial observation. In larger cells the astrosphere is always left free, and as the amount of cytoplasm increases the strands are more separated, become thinner and are not so basophile. But until the cytoplasm attains a very large size in the large mononuclears there is always some part or parts of it which show the original structure and deeper basophile staining. Ehrlich has himself noted that in the neutrophile series the younger cells are more basophile than the older.

2. The shape and staining of the nucleus. This, in leucocytes, is a matter of no importance. All are agreed that the neutrophile myelocytes and polymorphs belong to the same series, but what nuclei could be less alike than the pale oval one of the myelocyte and the dark twisted one of the polymorph? But not only is the polymorph derived from the myelocyte, but, as Ehrlich says, one has only to examine any film of pus to find that the polymorphous nucleus can and does become oval again, and, further, the eosinophile sputum of certain asthmas contains countless cells which, if they were in the blood or marrow, one would unhesitatingly call eosinophile myelocytes, though the eosinophiles in the blood of the same case all have polymorphous nuclei. M. Heidenhain's researches, which explain satisfactorily all the changes undergone by leucocyte nuclei, have met with far too little attention from both pathologists and hematologists. The cytoplasm consists of a ground substance in which are imbedded radii which have their center in the centrosomes, astrosphere, or attraction sphere. When the cell is in a state of rest the pull of these radii tends to bring the astrosphere to the center of the cell. The usual obstacle is the nucleus, and in cells with a small amount of cytoplasm, for example, lymphocytes, the pull is not strong enough to bring this about. As the cytoplasm increases in amount the pull becomes stronger, and the nucleus is pushed to one side and ultimately deformed, becoming first kidney shaped and finally horseshoe shaped, at which stage the astrosphere comes to rest in the center of the cell, for example, transitionals. But in some cases the cytoplasm is relatively very large in amount, and here the astrosphere can reach the center of the cell without causing any deformation of the nucleus, for example, large mononuclears. If a nucleus is about to divide, it probably usually swells up and reassumes the circular form first. If a cell begins to move, the nucleus moves with it, and may be secondarily deformed by movement—for example, polymorphs, eosinophiles, and some transitionals—and, of course, the more ameboid the cell the greater the deformation is likely to be. It will be obvious how this rule explains the shape of the nuclei of leucocytes, and why the nuclei of the more ameboid series (neutrophile, eosinophile, basophile) are so frequently polymorphous, while those of the lymphocytes, or less ameboid series, are only occasionally polymorphous, though transitionals have a polymorphous nucleus much more often than is supposed. The depth of staining of the nucleus in different cells depends on the spacing of its chromatin, in the same way as in the cytoplasm.

3. The presence of granules. The granules of the other series are really the nodal points of the reticulum of the cytoplasm, and Gulland's observations have since been confirmed by Arnold and others. In this sense all lymphocytes are granular, for there are nodal points in their cytoreticulum as in the others; but they are generally much less conspicuous, and in the smaller lymphocytes are often concealed by the thick strands. In the large lymphocytes, mononuclears, and transition-

als they often attain a considerable size, and it has been shown by studies with the Romanowsky stain and its modifications that they are not neutrophile, but take up the methylene-azure of that stain. Wolff, indeed, regards them as specific for the lymphocyte series, and their presence in all the above cells furnishes another proof of the identity of the different forms. That the granules cannot be demonstrated in all lymphocytes seems to depend on conditions of solubility not unlike those of the mast-cells, and one often finds negative pictures of them.

4. Size of the cells. The mononuclears are always large cells—their large amount of cytoplasm necessitates this—but some transitionals are no larger than a medium-sized lymphocyte. The size of the mononuclears and transitionals seems largely to depend on the taking up of fluid—in the blood at least—as the strands of the reticulum are often widely separated, and these cells are obviously soft, as may be seen from the way in which they are indented in films by the red corpuscles, which does not happen to the smaller members of the series.

The Function of Lymphocytes.—There is, of course, no doubt that they are largely protective, especially when present in lymph glands, etc. It is not yet settled whether those of the blood are directly protective, whether they are present there in process of being carried to reinforce lymphatic tissue, or whether they are nutritive, or have some other function. On the one hand, it is difficult to imagine that the millions present in the blood are concerned only with defence; on the other, the facts of leucocytosis show how rapidly the polymorphs have to be increased on occasion, and how great this increase may have to be. We are apt to forget that our bodies are constantly being attacked by organisms, and that illnesses represent only the more vigorous attacks attended with some measure of success. It is interesting to note that the main dépôts of lymphocytes, apart from lymph glands and marrow, are round the hollow tubes of the body, the alimentary and respiratory tracts, and that these are the places which are occupied by saprophytic, nonvirulent, or attenuated organisms. It seems possible that lymphocytes are adapted and sufficient to keep these in check. They are certainly not sufficient to resist virulent infections, which have to be met by polymorphs. Lymphocytes multiply so easily in connective tissue that the small percentage in the blood is enough for reinforcement and for direct protection there; polymorphs do not multiply well in connective tissue, hence their percentage in the blood must be higher.

The Etiology of Leucemia.—Dr. T. Gillman Moorhead, of Dublin, spoke on this subject. Since the first recognition of leucemia as a distinct clinical and pathological entity some sixty years ago, this disease along with most others that principally affect the blood-forming tissues, has remained an etiological puzzle, and, although many have investigated the subject and some few have attempted to produce the disease experimentally in the lower animals, no definite and confirmed result has as yet been reached. Of late, discussion and investigation has principally centered around the inter-relationships of the different diseases to which the generic term leucemia is applied, and attempts have been made to prove that they are all primarily diseases of the bone marrow. It was not his intention, however, to enter into this discussion, or to consider the supposed different functions and properties of the various forms of white blood corpuscles. It is sufficient to state that both the lymphatic and splenomedullary type of disease, appear to be essentially the result of morbid changes in the hemopoietic tissues, and that in both diseases, changes in all parts of these tissues may be expected to occur. The close physiological connection of the spleen, bone marrow, and lymphatic glands has indeed been shown by their universal reaction to lymphotoxic and myelotoxic serums as proved by Flexner. Moreover, the occurrence of cases, in which, as far as the blood itself is concerned, the type of disease changes, by a myelocythemia becoming converted into lymphocythemia, supports Flexner's results, and is referred to, in order to point out that in experiments attempting to produce either form of leucemia, the actual production of any changes in the hemopoietic tissues will have a positive value. The various theories that have been propounded concerning the etiology of the disease may be reduced to two, namely (1) the parasitic theory, and (2) the toxic theory. Writing in 1898, Robert Muir states that no parasite of the nature of the malarial organism has been observed in leucemia, and that there is no adequate evidence that any bacterium is concerned in the disease. Since that date, however, Löwit has described an ameboid organism which he calls the *Hæmamœba leucæmiæ magna*, and which he states can be demonstrated by special staining methods in the blood and tissues of patients suffering from splenomedullary leucemia. A similar but smaller organism, which he terms the *Hæmamœba leucæmiæ parva*, is to be found, according to the same observer, in the blood of lymphatic leucemia patients. These organisms are stated to form spores and to pass through stages very similar to those of the malarial parasite. They have not as yet been artificially cultivated. By injections of fresh tissues obtained from leucemia patients immediately post mortem Löwit claims to have produced in rabbits pathological changes which closely resemble those found in myelogenic leucemia, and to have found the hemameba in the diseased parts. Similar injections into dogs, cats, and guinea pigs did not produce any changes. These results have not as yet been confirmed, although it is now more than three years since the date of their publication. The author further spoke of the toxic theory and gave a series of his own experiments leading to no definite conclusions.

(To be Continued.)

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held November 14, 1904.

The President, T. E. Satterthwaite, M.D., in the Chair.

Cirrhosis of the Liver and its Treatment.—A discussion on this subject was the order of the evening, and it was opened by Dr. Leonard Weber. He said that in his experience fatty cirrhosis was almost as frequent as Laennec's. In the latter, after a more or less pronounced stage of hypertrophy, the liver begins to retract, and then, with or without periods of intermission, goes on to atrophy. He thought the hypertrophic form of cirrhosis, described by French writers, must be very rare in this country. He had never met with but one instance of this, although on two or three other occasions he believed that he had such a case under observation, but presently retraction set in. In Glissonian cirrhosis we have practically a perihepatitis. In atrophic

cirrhosis we have long been accustomed to consider the condition as a primary disease, and the accompanying splenic tumor as due to passive congestion; but quite recently it has been contended that this was a mistake and that hepatic cirrhosis should be placed in the category of blood diseases, along with anemia and leucemia. Under this hypothesis the enlargement of the spleen is of primary importance, and in the opinion of some the origin of the condition in the liver.

Statistics of Cirrhosis.—Dr. James K. Crook spoke of the importance of an early diagnosis, saying that if it was to be of use to the patient, the diagnosis should be made in the early stage of the disease. In considering the diagnosis one must inquire into the causation of hepatic cirrhosis. What are the factors producing it? In which sex, at what age, and under what conditions of life does it most frequently occur? In the records of the New York Board of Health for the last decade of the nineteenth century the ages of the patients dying from the disease are found to be as follows:

Under one year	9
Under five years	11
From 5 to 10 years	11
From 10 to 15 years	9
From 15 to 25 years	553
From 25 to 35 years	1061
From 35 to 45 years	1196
From 45 to 55 years	959
From 55 to 65 years	565
From 65 to 75 years	140
From 75 to 85 years	14

These figures corroborate observations previously made. While no period of life is exempt, by far the greater number of cases occur in adult middle life. Over 68 per cent. occur at this period and over 62 per cent. in males. Another point of interest is the nationality of the patients. In New York 26 per cent. of the cases referred to occurred in native born Americans, and 73 per cent. in aliens. Among the latter, the Irish are a little in the lead, but the Germans make a very close second.

Causation.—The use of alcohol is regarded as the leading cause of the disease, and so experienced an observer as Murchison stated that he had never seen a case except in those addicted to it. The strong distilled liquors are usually supposed to be especially productive of cirrhosis, but it is also found to be common among those principally using malt liquors, as the Germans, while Lancereaux attests its frequency in France, where the common beverage is vin ordinaire. Other causative factors were then referred to. Syphilis has been recognized as one ever since Virchow's classic work on the subject. Out of 37 cases at the Roosevelt Hospital, a syphilitic history was obtained in three. In countries like southern Italy, where malaria is endemic and chronic, there appears to be a clear connection between this affection and cirrhosis, but in climates such as ours the relation is difficule to trace. Osler states that at the Johns Hopkins Hospital he has never met with a case in which malarial disease resulted in cirrhosis. Other causes which have been assigned are typhoid fever, yellow fever, and other infectious diseases, and the use of highly seasoned food.

The Pathological Anatomy of Hepatic Cirrhosis.—Dr. Frank Grauer read a paper on this topic. The three most frequent forms met with are the atrophic, the hypertrophic, and the syphilitic. In the atrophic or multilobular, the common variety of the disease, the reduction of the size of the liver is not invariable. In many instances the organ retains its normal size, and sometimes it is moderately enlarged, this enlargement being due, as a rule, to fatty infiltration of the liver cell. The liver is tough and inelastic, and its external surface is marked by a number of hobnail-like projections of varying size. The whole organ is found to be beset with a network of cicatricial tissue enclosing rounded islands of liver substance. Each island is made up of several lobules, but the compression to which they have been subjected may render their individual recognition difficult or impossible. In the early type of the disease microscopical examination shows clear evidence throughout of inflammatory change in the tracts of the connective tissue which supports the ramification of the portal veins. The so-called portal canals are packed with leucocytes and connective tissue cells in a state of active proliferation, and here and there columns of fibrifying tissue may be seen advancing between the twin cells. By the junction of such columns a wide-meshed network of developing tissue comes into being throughout the entire organ. In the late stage this network is seen to consist of dense fibrous tissue which has generally lost the highly cellular character seen at an earlier period. Such tissue has a strong tendency to contract, and thus it compresses the liver cells contained in the lobules. Some of the latter undergo atrophy and absorption, so that there are formed extensive tracts of whitish gray color, consisting of fibrous tissue, with only a few isolated groups of hepatic cells. In advanced cirrhosis the liver cells are invariably degenerated. They are also filled with large fat globules (fatty infiltration). The branches of the portal vein become compressed, narrowed and obliterated, and in some cases there is an apparent development of a few bile ducts in the strands of the fibrous tissue. The condition of the blood vessels is remarkable. If the hepatic artery be injected, it is found that the new fibrous tissue, which looks quite bloodless, is abundantly supplied with vessels from that source. Occasionally there is seen evidence of an arteriosclerosis or an endarteritis obliterans of the hepatic artery. The portal veins may show thickening of their walls with a peri- or endophlebitis. The changes in other organs, due to the portal obstruction, are enlargement of the spleen, passive congestion of the stomach and intestines, induration and congestion of the pancreas, and ascites.

Hypertrophic Cirrhosis.—In hypertrophic or unilobular cirrhosis the liver is increased in size and weight. The surface is smooth or finely granular and of a tough consistence, but does not present the leathery hardness met with in the atrophic form. The capsule is often somewhat thickened, but there is seldom the degree of thickening or of perihepatitis seen in the latter. In the majority of instances the liver is jaundiced. The cut surface is more minutely subdivided than in the atrophic form, and the cicatricial bands are finer. Microscopically, a new development of fibrous tissue is seen throughout the organ, and this with considerable uniformity surrounds the individual lobules, while in many cases it invades the lobules to some extent from the periphery. The peripheral cells are thus separated from each other and from the lobules, so that they come to lie stranded in the new tissue. The cells thus implicated are usually in a state of atrophy. In nearly all cases a remarkable plexus of bile ducts, of varying size, is found embedded in the new tissue. The mode of origin of these ducts is somewhat obscure, and the explanation given by Cornil

is probably the most satisfactory. The question has often been raised whether in this form of cirrhosis the primary process is an interstitial inflammation, followed by secondary destruction of the secreting cells of the lobules, or a primary toxic atrophy of the epithelial cells, to which the fibrous growth is secondary; and the weight of evidence is strongly in favor of the atrophy being secondary.

Syphilitic Cirrhosis.—This may be either congenital or acquired. In the congenital form the liver is large, firm, smooth and mottled, and careful inspection usually shows throughout the whole organ the presence of grayish or white points and lines corresponding to the interlobular new growth. Microscopically, there is seen great increase of the connective tissue, while in many places foci of small-celled infiltration are found. The new tissue passes within the lobules and between the liver cells, often surrounding and isolating individual cells (the so-called pericellular cirrhosis). Miliary and large gummata may be present. In the cirrhosis resulting from acquired syphilis, also there are fibrosis and gummata. In the early stage the latter are pale and grayish nodules, varying from the size of a pea to that of a marble. The large ones present yellowish centers at first, but later there is a pale yellowish cheese-like nodule, surrounded by a fibrous zone, the outer edge of which loses itself in the lobular tissue, which generally diminishes and becomes destroyed. The gummata show a tendency to undergo fibrous change, and when numerous they produce by their gradual healing the most extensive deformity of the liver. Occasionally the syphilitic changes are manifested in a thickening of the capsule, producing a perihepatitis and increase in the connective tissue of the portal canal.

Surgical Treatment.—The discussion on the surgical treatment was opened by Dr. Robert T. Morris. In certain cases of hepatic cirrhosis, he said, the production of venous anastomosis, as advocated by Talma and later by Morrison, appeared to be called for. Personally he had operated in seven cases, all of alcoholic origin. In two of these the cirrhosis was hypertrophic, and in both the result had been very satisfactory. In the five cases of atrophic cirrhosis the results were not satisfactory, four of the patients having died. In the fifth case he hoped for a better result, but only a short time had now elapsed since the operation. In cirrhosis the average duration of life after the occurrence of ascites is dated to be six months, and in the four patients operated on who died it was not as long as that. They appeared to feel better as the result of the operation, but this may have been merely a mental effect. Dr. Morris thought it important that the operation for making the venous anastomosis should be performed in as short a space of time as possible, as this class of patients did not stand shock well. He would allow but ten minutes for the whole operation. In order to save time he was accustomed to use a brush, which he had devised, for quickly removing endothelium. It was also important to close the abdomen immediately after the operation, instead of using drainage. Dr. Weber had expressed the opinion that the relief from ascites was practically due to the mere opening of the peritoneum, as in peritoneal tuberculosis. In tuberculosis the hyperleucocytosis, thus produced, was destructive to the bacilli; but in cirrhosis the condition of affairs was different, and venous anastomosis appeared to be called for.

Dr. George R. Fowler reported a case operated on during the past summer by Dr. Russell S. Fowler. The patient, a man of fifty-six years, was admitted to the medical service of the Brooklyn Hospital on July 24. He acknowledged being moderately addicted to alcohol, but denied having had syphilis. One year ago he began to suffer from what he called malaria, and about the first of May his abdomen commenced swelling. At the time of admission it was enormously distended, and after having been tapped twice, he was transferred to the surgical service of the hospital. Examination showed the liver to be small and the spleen slightly enlarged. On August 24 a median laparotomy was performed, the incision extending ten and a half inches downward from the xiphoid cartilage. A very large amount of serous fluid having been evacuated, the liver and spleen were scarified with a piece of rough crash, like Turkish toweling, and also with the edge of the knife. The round ligament was then shortened, and the liver sutured with chromic gut to the abdominal wall and the diaphragm. The omentum, which was small, was also sutured to the abdominal wall, from side to side, and finally the abdomen was closed with crossed sutures of chromic gut. Ascites returned during the first week after the operation, and was absorbed during the third week. In the second week a hypostatic pneumonia supervened, and the patient was kept constantly in a sitting posture. Since that time there had been no further accumulation of fluid. He was discharged September 28, and is now in good condition. This patient was presented by Dr. Fowler to the Association. Dr. Fowler went on to say that ascites, occurring in the course of cirrhosis of the liver, is looked upon as a direct result of obstruction to the portal circulation, due to the pathologico-anatomical changes incident to the disease. Without doubt a certain amount of obstruction to the circulation in the liver is tolerated by the general intra-abdominal circulation and compensated for by the presence of anastomosing veins between the systems of the portal vein and the inferior vena cava. That these are not sufficient for the purpose in all instances of hepatic cirrhosis is now generally admitted; but that a large number of cases of this disease are thus properly compensated is shown by the statistics of Lange, who records that out of 115 fatal cases of cirrhosis, in 65.6 per cent. there never was any ascites. Therefore, it may easily happen that there will be all degrees of compensation in different individuals, as well as all grades of demand for such compensation; from the patient with but slight need for the existence of compensating vessels—and yet the latter insufficient for such need—to the case in which the obstruction is considerable—and yet the anastomosis sufficient to meet the demands made upon it. The object of the Talma operation is to strike the balance, as it were, between the obstruction as it exists and the facilities afforded by the natural channels for compensating for the obstruction. Without doubt there is more or less compensatory dilatation of these already existing channels in some cases, as shown by the development of the caput medusae. That these finally fail in a certain proportion of instances is likewise true. It is also a fact that even with the additional channels afforded by the operation, only about one-third of the cases operated upon remain free from ascites. Greenough's statistics show 60 per cent. of failures, these being about equally divided between those who died as a result of the operation and those who were not improved by it. As to the dangers of the operation, there is a mortality of nearly 30 per cent. attached to it; to

say nothing of the risks of auto-intoxication attending the diversion of a certain amount of blood from the mesenteric veins directly into the general circulation, as shown by the experiments of Eck, Hahn and Tillmann.

Rationale of the Talma Operation.—The rationale of the operation depends upon the development of vessels of communication between the portal system and the general system directly. This may not be demanded early in the case, and may never be required. When the normal channels prove insufficient the operation should be done at once; not waiting for repeated tappings and hence great debility of the patient. In order to attain all that can be accomplished by the operation, in addition to substituting it for the second or third tapping at the most, care should be taken to provide adhesions sufficient in extent, and the vessels of which, dilating as the demand is made upon them, may serve to maintain the balance between the obstruction on the one hand and the intra-abdominal vascular tone on the other.

Many Tappings Sometimes Tolerated, and with Benefit.—Dr. Frank Grauer said that in his own experience Hale White's dictum was not borne out, and patients could sometimes stand many more than six tappings. He had in mind particularly a case which came under his care in January, 1899. He was seen in consultation by Dr. A. A. Smith, who thought the case a very bad one and expressed the opinion that the man could not live more than three months. He had atrophic cirrhosis and was suffering from diarrhea and marked ascites. At the first tapping 5½ gallons of fluid were withdrawn and some days later, at the second tapping, nearly five gallons more. Later in the year the patient was seen by Dr. E. G. Janeway, who thought he might perhaps live six months longer. Between January, 1899, and December 20, 1900 he was tapped, in all, 21 times, the amount of fluid withdrawn at the different tappings varying from three to five gallons. For nine months after the last tapping there was no return of the ascites. At the end of that time he suffered from an attack apparently brought on by an overindulgence in the pleasures of the table, and died from auto-intoxication.

BOOK REVIEWS.

Radiotherapy and Phototherapy, including Radium and High Frequency Currents, their Medical and Surgical Applications in Diagnosis and Treatment. By Charles Warrenne Allen, Professor of Dermatology in the New York Post-Graduate Medical School, with the cooperation of Milton Franklin, M.D., and Samuel Stern, M.D. Lea Brothers & Company, New York and Philadelphia.

It is a striking illustration of the energy of the mind of the medical man to find no less than five or six large works on radio and light therapy, that have been published in very recent years.

The time had seemed ripe when the general settings of the whole problem had been dimly outlined, and in Dr. Allen's work we think we find for the first time a sense of the perspective of the whole subject of light therapy, as it now appears.

From the practical point of view the practitioner will find an able and thoroughly practical work, not on X-ray work as applied to the diagnosis of disease, but of the whole subject of the physiological and pathological relationship of light energy manifestations.

It can be commended most heartily and Dr. Allen himself should be congratulated on the excellent showing he and the publishers have made of this most fascinating subject.

A Treatise on Bright's Disease and Diabetes. With special reference to Pathology and Therapeutics. By James Tyson, M.D., Professor of Medicine in the University of Pennsylvania, etc. Second Edition, Illustrated. Including a section on the Ocular Changes in Bright's Disease and in Diabetes. By George E. de Schweinitz, M.D., Professor of Ophthalmology, in the University of Pennsylvania. P. Blakiston's Son & Co., Philadelphia.

It is now fully thirteen years since the first edition of this work originally saw the light, and the book has now been out of print for many years. Necessarily, the second edition varies in many very important particulars from the first, for the intervening period has been rich in contributions, especially to the theory of the so-called "Stoff-wechsel" diseases. However, the diagnosis and treatment of renal conditions have considerably amplified and improved. It may be cheerfully conceded that everything of value has been incorporated in this second edition, although the original plan and scope of the work has simply been enlarged to accommodate this new material. It is still characterized by its tendency to seek a pathological basis for the clinical conditions, a standpoint which puts it on an equal footing with the best that is being written in Germany at the present day. The sections on the eye-symptoms are an extremely valuable constituent of the work, and have very properly been entrusted to the hand of a specialist. The therapeutics are simple, yet full, and calculated to meet all the emergencies of this protean disease. The illustrations, with the exception of the colored plates representing pathological conditions of the kidneys, are in general excellent, and the make-up of the book leaves nothing to be desired.

The Doctor's Red Lamp. (The Doctor's Recreation Series. A book of short stories concerning the doctor's daily life, selected by Charles Wells Moulton. The Saalfield Publishing Co., New York, Chicago and Akron, Ohio.

This volume contains a number of very interesting sketches illustrating the physician's many points of contact with life in its various phases. There is the "Doctor of the Old School," by Jan Maclaren, and one of Dr. Conan Doyle's medical stories and Margaret Oliphant's Dr. Barrere, as examples of the familiar, though also as an index of how well selections are made. Physicians and their wives may well pass some very pleasant hours in the reading of these sketches, which are printed on excellent paper, in good, large, untiring type, so that one is tempted to take the book up when other books pall. There are some well reproduced illustrations of incidents in medical life to add to the interest.

Transactions of the American Climatological Association. Vol. xx, 1904.

This volume of transactions contains, as usual, many articles of interest to more than the specialist in climatology. We note among others articles by Dr. J. O. Cobb, of Los Angeles, on "Is Milk a Factor in Tuberculosis," by Dr. Rob't B. Babcock, of Chicago, on "Cases of Pus Infection Simulating Pulmonary Tuberculosis," by Dr. Jno. W. Brannan, of New York, on the "Home Treatment of Tuberculosis by Means of Hospital Dispensaries," and "The Work of the Tuberculosis Clinic of the Health Department of New York City," by Commissioner Darlington.

A Text-Book of Diseases of the Nose and Throat. By D. Braden Kyle, M.D., professor of Laryngology and Rhinology, Jefferson Medical College; Consulting Laryngologist, Rhinologist and Otologist, St. Anges' Hospital, etc. With 175 illustrations, twenty-four of them in colors. Third edition, revised and enlarged. W. B. Saunders & Co., Philadelphia, New York and London.

The third edition of this excellent work presents much new material. Among the alterations and additions those of especial interest are in the chapters on keratosis, epidemic influenza, Gersung's paraffin method for the correction of nasal deformities and the X-ray treatment of carcinoma.

A new departure is the extensive fund of information on the chemistry of the saliva and the nasal secretions and its bearing on diagnosis and treatment. The author's laboratory researches in this department are practically utilized in the discussion of hay-fever, the prognosis of which he regards somewhat more optimistically than many other writers. The discussions accorded to the treatment of each condition are especially valuable and should be of much assistance to the non-specialist on account of their completeness and descriptive detail. Full attention is also accorded to the more purely scientific aspects of the subject and the pathological anatomy of the diseased tissues is well described and illustrated, in many instances by beautifully reproduced colored plates of stained sections.

From every standpoint the book is thoroughly satisfactory and will be found a reliable and practical guide by all classes of readers.

The Summer Diarrheas of Infants, their Etiology, Pathology and Treatment. By H. Illoway, M.D., formerly Professor of Diseases of Children, Cincinnati College of Medicine and Surgery, etc. E. R. Pelton, New York.

The author devotes much space to arguments to prove that the general classification of summer diarrheas is wrong, largely because many of these diarrhea occur also, though much less frequently, in the winter months. He maintains that there are types of diarrhea that are never met with except during the heated months of the year, and to these alone should the term "summer diarrhea" be applied. He calls attention also to the fact that infants almost dying from summer diarrhea, may take a new lease of life from a short outing of a few hours, that no lesions are found in the bowels except in cases of long standing, and that the diseases are non-inflammatory in character. He groups all true summer diarrheas under three heads: Cholera Infantum, Summer Complaint, and Heat Stroke or Thermic Fever. The book is of a size to be easily carried in the pocket. It is to be regretted that the controversial style of the author makes him write as if repeatedly challenging the opinions of his fellows in the pediatric field.

The Mother's Manual. By Evelyn Lincoln Coolidge, M.D. The Woman's Home Library Series. A. S. Barnes & Co., New York.

Although it is probable that, should this little volume be widely read and its precepts put into active practice by mothers and nurses, the pediatrician and the "family doctor" might find their annual income somewhat depleted, it will probably be very well received by the profession, and should be in a fair way to gain the measure of success which it certainly merits. The author writes simply, and the book throughout is unusually free from technical terms; she does not "gush," but on the other hand, the book may be designated, in the best sense of the term, as "popular" without being puerile. Dr. Coolidge is thoroughly at home in her subject, as she already ranks as an authority in matters relating to the care and training of little children, and the good sense and sound advice contained between the covers of this little book ought to lighten the burden of many an anxious young mother, and incidentally secure an overworked physician some much needed nights of unbroken sleep, which would otherwise be disturbed by the frantic message that "there is something the matter with baby, and I don't know what."

Essentials of Nervous Diseases and Insanity: Their Symptoms and Treatment. By John C. Shaw, M.D., late Clinical Professor of Diseases of the Mind and Nervous System, Long Island College Hospital Medical School. Fourth Edition. Thoroughly revised by Smith Ely Jelliffe, Ph.D., M.D., Clinical Assistant, Columbia University, Department of Neurology; Visiting Neurologist, City Hospital, New York. W. B. Saunders & Company, Philadelphia, New York and London.

There is probably no book of the same size, in English at least, which gives such clear cut and definite ideas with regard to the knotty subjects of nervous and mental diseases as does this little Question Compend on the essentials of nervous diseases and insanity. Many a physician who has considered that the problem of learning to differentiate, to some degree at least, these affections, is too complex, will by surprised to find how much can be put in a short space and thus readily learned by means of this little volume.

The fourth edition of the book has been brought thoroughly up to date and noteworthy additions have been made both as regards nervous and mental diseases. There seems no doubt that the work will continue to have, and even to increase the popularity which it has heretofore enjoyed.

Electro-Diagnosis and Electro-Therapeutics. By Dr. Toby Cohn. Translated by Francis A. Scratchley, M.D., Consulting Neurologist to the Home for Incurables. Funk and Wagnalls Company, New York and London.

To all workers in neurology Cohn's work has been a standard for a number of years. Its appearance in English is a matter of congratulation for, while many works on the subject are available, there is hardly one of which it may be said that it is concise and practical. Whether Electrotherapeutics leads to much writing and little thinking or not is a mooted question, but certainly Cohn's work is nearly all meat, very little superfluous padding."

Elements of Water Bacteriology, with Special Reference to Sanitary Water Analysis. By S. O. Prescott, Assistant Professor of Industrial Biology, and Charles E. Winslow, in Massachusetts Institute of Technology. John Wiley & Sons, New York.

So much rubbish is being written about sanitary water analysis that it is a comfort to find a short, sensible treatise like unto the present one. It is, however, very incomplete, and deals only with a few of the organisms of water.

We hope to find that the authors, in a second edition, will give us a larger work, on the order of Frankland, and that they will also include systematic differentials as in Chester's Manual.
